PREFACE

Food is probably man's primary interest in times of peace and his main worry in times of stress such as wars and economic depressions. During these times, every effort is made to maintain and increase food supplies by relief and victory gardens. New methods of food preservation are introduced, in addition to those used during times of peace. Some well-known methods have had their origin in times of wars. The canning industry, for instance, originated in the desires of Emperor Napoleon to have new sources and supplies of food when he was moving vast armies across the face of Europe. Appert was stimulated to study the problem and won a prize for his suggestions which started interest in sealing foods in containers and subjecting them to heat. Great progress has been made since then because it has been possible to use such sciences as physics, chemistry, and bacteriology on problems of the food industry. As these words are being written the Allied Armies are receiving better foods in the field than armies have ever before received. Many of the foods are preserved and packed in new ways.

Since publication of the first edition of this book, many advances have been made in the science of bacteriology and especially in its application to foods. These have made it necessary to completely rewrite the book. The subjects of mycology and microbiology have been greatly expanded. Since it is intended that this book be a source book to the literature as well as to methods of analysis, much of the recent literature has been reviewed. References are at the bottom of the pages containing the context which they support.

The present edition includes all major methods of analysis which have been issued up to the time of publication. Especially to be mentioned are "The Bacteriological Examination of Water Supplies" and "Bacteriological Tests for Graded Milk" prepared by the Ministry of Health of Great Britain, arrangements for reproduction of which in this book were made with His Britannic Majesty's Stationery Office, London, from which original copies may be purchased; also to "British Standard Methods for the Microbiological Examination of Butter," prepared and published by the British Standards Institution of London. The author is, also, grateful to the Association of Official Agricultural Chemists for permission to include procedures of analyses of various foods which have been published in the Association's Journal. References to these methods are given in the text.

The literature of food microbiology and technology has expanded during recent years. Such publications as *Food Research*, the *Journal of Dairy Science*, the *Journal of Dairy Research*, *Journal of the American Dietetic Association*, *Cereal Chemistry*, the *Analyst*, not to mention many others, and the regular publications of various scientific associations, such as the American Chemical Society, Society of American Bacteriologists and the Institute of Brewing, publish results of original investigations on which the science is based. In addition are good trade association publications.

The Annual Reports of the Food Investigation Board of Great Britain and the *Special Reports* of the same institution should not be overlooked by the food microbiologist who is up-to-date. Numerous reference publications, such as *Chemical Abstracts*, *Biological Abstracts*, *Experiment Station Record*, *Index to the Literature of Food Investigation*, are also available to help those who "search the literature."

Little emphasis has been given in this volume to food infections and intoxications because these subjects are covered in a companion volume, "Food-Borne Infections and Intoxications" published in 1933. A new edition of this book is being prepared for publication sometime in the future. This problem is of far less importance than some are prone to believe. Billions of pounds of food are processed and distributed in the United States without causing illness.

Food technology has profited greatly by activities of many laboratories supported by trade associations and private industrial concerns, in addition to laboratories in academic institutions. Many could be mentioned from which come reports of results of experimental work carried on under the best of conditions. Typical of them are the research laboratories of the National Canners Association and the Institute of Paper Chemistry. The former does much work which benefits not only the industry from which it receives its main support, but others as well. The latter has done much to improve paper wrappings for foods and is thus contributing to better and safer living. In addition are the many research laboratories supported by private industrial concerns in whose laboratories are the best trained men available. In such laboratories talent from various sciences is available on all problems.

Owing to the time required for manufacturing this book, it has been possible to include more recent literature citations in the later chapters than was possible in the early ones.

The author also gratefully recognizes the assistance of his wife, Dr. Louise Pickens Tanner, who has assisted with the manuscript and proof, and who has been a constant source of inspiration and helpful frank criticism during the preparation of this book. Special acknowledgment is given to Mrs. Blanche Young and to Mr. James Garrard of my publishers, without whose constant interest and helpful suggestions the work would have been more difficult; also to Mr. Van Easterday, Jr., Mr. Leo Althaus, and Mr. Neil Covington, results of whose technical skills are apparent in every page.

FRED W. TANNER.

TABLE OF CONTENTS

	PAGE
CHAPTER 1. FOOD PRESERVATION	1
Asepsis, Chemical Preservatives, Low Temperatures, Freezing, High Temperatures, Fermentation, Dehydration, Carbon Dioxide, Ozone, Ultraviolet Light, Spices, Food Standards and Food-Control Acts, Adulterated and Misbranded Foods, Wrapping and Packaging, Methods for Examining Paper.	
CHAPTER 2. THE BACTERIA	59
Staining Reactions, Heat Resistance, Fermentation Reactions, Fat Decomposition, Thermal Death Time, Thermal Death Time Curve, Groups of Bacteria.	
CHAPTER 3. YEASTS AND MOLDS	110
Resistance of Molds, Rhizopus, Mucors, Penicillium, Thamnidium, Botrytis, Dematium, Citromyces, Aspergillus, Sachsia, Fusarium, Cladosporium, Sporotrichum, Wardomyces, Claviceps, Oidium, Marginomyces, Actinomyces, Endomyces, Byssochlamys, Sporendonema, Monilia, Yeasts and Yeast-Like Fungi, Classification of Yeasts, Methods of Studying Yeasts, Classification of Yeasts.	
CHAPTER 4. BACTERIOLOGY OF WATER AND SEWAGE	✓ 156
Bacteriological Examination of Water, Streptococci as Indicators of Pollution, Anaerobic Bacteria, Coliform Group, Presumptive Test for Coliform Bacteria, Direct Enumeration of Coliform Bacteria, Citrate Fermentation, Longevity of Coliform Bacteria, U. S. Public Health Service Standards, Sterilization of Water, Bacteriophage, Bacteriology of Ice.	
CHAPTER 5. MICROBIOLOGY OF MILK	✓ 250
Bacteria in Milk, Sanitary Condition of Glass Bottles, Streptococci in Milk, Hemolytic Streptococci, Leucocytes, Flavors, Certified Milk, Dirt, Grading.	
CHAPTER 6. BACTERIOLOGICAL MILK ANALYSIS	✓ 320
"Bacterial Count" of Milk, Prescott-Breed Method, Frost's Method, Coliform Bacteria, Methylene Blue Reduction Test, Resazurin Test.	
CHAPTER 7. PASTEURIZATION OF MILK	✓ 391
Definition, Methods, Bacteria in Pasteurized Milk, Phosphatase Test, Pathogenic Bacteria.	
CHAPTER 8. MICROBIOLOGY OF CREAM AND BUTTER	✓ 448
Methylene Blue Reduction Test for Cream, Molds in Cream, Pasteurization of Cream, Phosphatase Test, Cream Ripening, Flavor of Butter, Deterioration of Butter, Flavors, Microbiology of Butter, Methods of Examination, Yeasts in Butter, Molds in Butter, Margarine.	
CHAPTER 9. MICROBIOLOGY OF CHEESE	✓ 503
Phosphatase Test, Ripening, Flavor, Bacteriophage, Blue Cheese, Brick, Swiss, Limburg, Processed Cheese, Mold on Cheese, Methods of Examination.	
CHAPTER 10. MICROBIOLOGY OF FROZEN DESSERTS, ICE CREAM, AND SIMILAR PRODUCTS	519
Origin of Microorganisms, Homemade Ice Cream, Ice Cream Mix, Pasteurization, Phosphatase Test, Bacterial Count, Aging, Sherbets and Ices, Bacterial Examination, Coliform Bacteria, Carbonated, Pathogenic Bacteria.	
CHAPTER 11. MICROBIOLOGY OF CONCENTRATED MILKS	✓ 552
Sweetened Condensed Milk, Evaporated Milk, Spoilage of Canned Milks, Bacteriological Examination, Dehydrated Milk, Microbiological Examination of Milk Powder, Standards.	
CHAPTER 12. FERMENTED MILKS	✓ 569
Lactic Acid Bacteria and Intestinal Therapy, <i>Lactobacillus acidophilus</i> , Acidophilus milk, Therapeutic Use of Acidophilus Milk, Buttermilk, Kefir, Kumiss, Leben, Mazun, Taette, Yogurt, Kuban.	

CHAPTER 13. INTESTINAL MICROBIOLOGY	
Intestinal Flora of Childhood, Diet, Fasting, Low-Protein Diet, Copious Water Drinking, Hydrogen Ion Concentration, Carbohydrates, Mouth, Stomach, Intestines, Bacteria and Life, Vitamin Synthesis, Destruction of Vitamins, Bile, Fecal Flora, Methods.	
CHAPTER 14. MICROBIOLOGY OF FRUITS AND FRUIT PRODUCTS	
Microorganisms on Fresh Fruits, Disinfection of Fruits, Drying, Pasteurization of Dried Fruits, Sulfur Dioxide, Frozen Fruits, Howard Method, Fruit Juices, Apple Juice, Orange Juice, Souring of Figs and Dates.	
CHAPTER 15. MICROBIOLOGY OF VEGETABLES AND VEGETABLE PRODUCTS :	
Microorganisms on Fresh Vegetables, Coliform Bacteria, Sterilization, Sewage Sludge, Dehydration, Frozen Vegetables, Analysis, Vegetable Juices.	
CHAPTER 16. MICROBIOLOGY OF TOMATO PRODUCTS	
Canned Tomatoes, Tomato Juice, Spoilage, Tomato Puree, Tomato Pulp, Tomato Catsup, Howard and Stephenson's Method, Standards, Insect Fragments.	
CHAPTER 17. MICROBIOLOGY OF BREAD	
Types of Bread, Microbiology of Flour and Meal, Toxins in Flour, Yeast Cells in Bread Dough, Defects of Bread, Mold Inhibitors, Yeast Foods.	
CHAPTER 18. FERMENTED FOODS	
Vinegar, Sauerkraut, Pickles, Olives, Tea, Cocoa and Chocolate, Coffee, Poi, Citron.	
CHAPTER 19. MICROBIOLOGY OF SUGAR AND SUGAR PRODUCTS	755
Gum, Raw Sugar, Molasses and Sirups, Honey, Candy.	
CHAPTER 20. MICROBIOLOGY OF FISH AND SHELLFISH	780
Fish Muscle, Halibut, Coliform Bacteria, Codfish, Preservation of Fish, Freezing of Fish, Canned Marine Products, Examination of Canned Fish, Sardines, Shellfish, Oysters, Examination of Shellfish, Mussels, Crabmeat.	
CHAPTER 21. MEAT AND MEAT PRODUCTS	838
Meat Inspection, Microorganisms in Meat, Gas Storage, Refrigeration, Deteriorations of Meat, Frozen Meat, Tenderization, Ground Meat, Sausage, Beef, Smoking, Salting, Drying, Curing, Hams, Bacon, Meat Pastes, Bacterial Examination, Canned Meats, Jellyed Meats, Poultry.	
CHAPTER 22. MICROBIOLOGY OF EGGS AND EGG PRODUCTS	911
Grading, Molds in Eggs, Enzymes, Chinese Eggs, Rot, Egg-Shell, Egg White, Egg Yolk, Liquid Eggs, Frozen Eggs, Dried Eggs, Preservation and Storage, Methods of Analysis.	
CHAPTER 23. MICROBIOLOGY OF CANNED FOODS	945
General Procedures of Canning, Heat Penetration, Sterilizing Processes, Cooling, Containers, Home Canned Foods, Microorganisms in Canned Foods, Spoilage of Canned Foods, Methods of Examination, Spoilage.	
CHAPTER 24. MICROBIOLOGY OF MISCELLANEOUS FOOD PRODUCTS	1005
Olive-Oil, Salad Dressings, French Mustard, Coconut Oil, Carbonated Beverages, Nut Meats, Spices.	
CHAPTER 25. MICROBIOLOGICAL METHODS OF ASSAYING FOODS FOR VITAMINS	1022
Thiamine, Riboflavin, Pantothenic Acid, Biotin, Avidin, Inositol, Pyridoxin, Folic Acid, Niacin (Nicotinic Acid), p-Aminobenzoic Acid.	
CHAPTER 26. CULTURE MEDIA	1102
Constituents, Reaction, Bouillon Media, Agar Media, Endo's Medium, Gelatin Media, Potato and Starch Media, Synthetic Media, Milk Media, Yeast Media, Media for Cultivation of Yeasts.	
INDEX	1169

THE MICROBIOLOGY OF FOODS

CHAPTER 1

FOOD PRESERVATION

Food is one of the few necessary requisites in life. Much of primitive man's time was spent searching for it. Later, complexities of life made it desirable for him to use some of his time for other things and compelled him to save the abundance of "the hunt" for times of need. The first methods employed to preserve foods were probably drying and smoking. Early man shared with his family or clan the duty of providing for the family food needs. As time passed and specialization became the order, only relatively few men gave their entire attention to various vocations involved in supplying foods. Early man was concerned mainly with quantity. Today man is concerned also with quality and recognizes among food problems those relating to purity and cleanliness of foods supplied the public.

When specialization was introduced, unscrupulous individuals tried to profit by cheating their fellows. Today sophistication involves problems usually discussed under two names—misbranding and adulteration. These terms are fully defined in food and drug control acts. While neither of them is as common as it once was, they do occur. Some treatments which are applied to foods should probably not be considered as adulteration; for example, some oranges are dyed and waxed to improve their appearance. Such a practice is objectionable only if it conceals inferiority or misleads the consumer into believing that he is getting better fruit. The issue may be properly raised when dyeing is used to make green fruit look like ripe fruit. Dyeing is permitted in some places in order that oranges raised in one section of the country may compete on a more even basis with those raised in another section.

Offenses against esthetic taste and decency are also encountered by food control officials. These involve such things as worm infestation, preservation of decomposed foods, and insanitary methods of preparation and handling. Some of these more general problems have been discussed by Howell.¹ Insanitary methods of handling and preparation are not limited to those who work with foods on a large scale; for instance, foods prepared for church suppers or sold at food sales of charitable organizations may be prepared and handled under insanitary conditions. Outbreaks of disease have been traced to foods obtained on such occasions and health officers in a few cases have tried to supervise them. Lessem² issued permits to organizations conducting sales of bakery goods. He insisted that they be prepared and handled under clean conditions.

1. Howell. 1936. J. Roy. San. Inst. 58, 292-297.

2. Lessem. 1938. Calif. State Dept. Health, Weekly Bull., Dec. 31, 1938.

The object of preservation is to keep foods for relatively long times as near their natural state as possible. Practically all methods, however, leave their stamp on the product through altered flavor, appearance, or texture. In some cases, quality of the product may be improved. Preservation may involve holding the food for years or only for some immediate emergency. On the basis of time Barcroft³ arranged foods in three groups: (1) those which can be kept for 10 years or longer; (2) those which can be kept for 10 months; and (3) those which can be kept only for the duration of a voyage, about two months. Grains are in the first group. Wheat may be stored for many years; some wheats will keep better than others. A major problem is weevil infestation. The moisture content of wheat is near 15 per cent while that of flour is about 11 per cent. Flour may be stored for quite long times in tin cans where it is inaccessible to weevils. Canned foods, also, fall into the group of foods which may be stored for long periods. In the middle group of foods with only moderate keeping qualities are dried milk and the root vegetables. Eggs may be kept for long periods in cold storage in an atmosphere of carbon dioxide of two to two and a half per cent. Foods which have only short-term storage possibilities are fresh meats and fish. When they are frozen solid, however, their storage life is greatly prolonged. The need of giving more attention to the effects of preservation procedures on the vitamin content of foods is now recognized. Rahn,⁴ grouped foods according to their chemical constitution which largely determines the types of microbial deterioration and the methods of preservation.

The many methods of food preservation may be classified in various ways; some of the more common methods are given below.

- | | |
|-------------------------------------|-----------------------------|
| I. Asepsis | IV. High temperatures |
| II. Addition of chemical substances | A. Pasteurization |
| A. Sodium benzoate | B. Boiling |
| B. Salt or sugar, or both | C. Canning |
| C. Spices | V. Fermentation |
| D. Acids (vinegar, sour milk, etc.) | A. Sauerkraut |
| E. Smoking | B. Pickles |
| III. Low temperatures | C. Milk (fermented milks) |
| A. Refrigeration | VI. Abstraction of moisture |
| B. Slow-freezing | A. Meats |
| C. Quick-freezing | B. Vegetables |
| | C. Fruits |

FRESH FOODS AND ASEPSIS

Fresh foods are those which are in their natural state and which have not been subjected to some special treatment to preserve them. Refrigeration may, perhaps, be an exception. Ordinarily, as applied to foods the term "fresh" means newly produced, harvested, or gathered. Examples are the leaf vegetables, fruits, and eggs. "Fresh" is also used to indicate foods which have not been preserved with salt, or foods from

³ Barcroft. 1939. *Brit. Med. J.*, Aug. 12, 1939, 324-327.

⁴ Rahn. 1913. *Centbl. Bakt.*, Pt. 2, 37, 492-497; Kuhl's *Hilfsbuch der Bakteriologie*. Leipzig, 1920.

which the salt has been removed by soaking in water. It is probably best to retain the word "fresh" for natural foods which have been recently harvested. Problems immediately arise, however, as to how this condition can be carefully measured so far as eggs and meats, for instance, are concerned. In the United States fresh foods probably present few hazards to health. Vegetables are not usually raised, as they are in certain foreign countries, on land which has been fertilized with human excreta or domestic sewage. Use of sewage sludge from treatment plants may introduce certain hazards, the magnitude of which, is probably not known today. Tanner⁵ reviewed results of investigations on survival of *Eberthella typhosa* in sewage sludge and soil and concluded that, while there is probably little actual danger in using sewage sludge as a fertilizer, it should be used with caution.

Foods which are rid of microorganisms, and kept so, will not undergo microbial spoilage, but some of them may be susceptible to chemical spoilage. Some fruits which are freed from living microorganisms by processing in tin containers do not spoil from action of bacteria. However, chemical reactions may cause losses of color, flavor, and texture. Efforts are now made to keep foods as free as possible from undue numbers of microorganisms. In some cases this effort is carried to an extreme. Foods with a low number of bacteria will have less opportunity of harboring undesirable species than those with a larger number. Furthermore few microorganisms mean lighter loads on preserving processes to be used later. Ample proof of this are the advances which have been made in the canning industry. This does not mean, however, that low numbers always mean high quality. Nature has used asepsis for preservation of various products. Starches are packed in sealed packages which are not broken by microorganisms under ordinary conditions. Fruits and vegetables are also covered with an impervious skin which resists microbial invasion.

Freshness is a quality of food which resists absolute definition. With fruits and vegetables freshness implies crispness and firmness and is related to water content. With meat and dairy products it may be more often associated with chemical and microbial phenomena. As chemical and microbial changes occur, these products lose their freshness.

Satisfactory procedures for determining freshness of foods have been difficult to find. Proctor and Greenlie⁶ suggested a modified resazurin technic for detecting large numbers of bacteria, the assumption being that large numbers of them could be used as an index of age. They compared bacterial plate counts and resazurin reduction rates of fresh and frozen foods, including ground meat, fish, crab meat, eggs, and vegetables, for the purpose of determining whether the use of redox-potential indicators offers a relatively accurate and prompt evaluation of quality. Their procedures need not be given here. Foods which had high bacterial plate counts, i.e., over one million per gram, had reduction rates such that the

5. Tanner. 1935. Sewage Works J., 7, 611-617.

6. Proctor and Greenlie. 1939 Food Research 4, 441-446.

color changes of the dye could usually be noted within three to five hours of incubation. In the case of foods with very high plate counts reduction was complete, or almost so, in 30 minutes. Proctor and Greenlie believed that a modified resazurin procedure might be used by food control officials and others for detection of foods having abnormally high bacterial contents or foods which have been improperly handled or stored.

It is difficult to distinguish between essential and unessential procedures for restricting microorganism content of foods. In the dairy industry, for instance, barn and stable conditions were once supposed to greatly influence the bacterial content of milk. However, it was found that milk from dirty barns had no more bacteria than milk from clean barns. This did not mean that stables may be neglected but that the real origin of bacteria in milk had not been discovered. Further experiments in the dairy industry showed that utensils contributed most of the bacteria to milk. Every effort should be made to have foods prepared and handled by clean people, and one of the best methods of gaining this end is to have clean physical plants. In some food industries, it is necessary even to filter the air which comes into the plant to remove mold spores that may infect the food.

CHEMICAL PRESERVATIVES

As soon as it was established that certain chemical substances were lethal to microorganisms or would suppress their development, suggestions were made to add them to foods to prevent spoilage generally considered to be caused by microorganisms.) Of the various chemicals proposed, only sodium benzoate is now permitted and its use is being curtailed. Sulfur dioxide is permitted in dried fruits under certain conditions. The fact that foods can be made to keep by better methods of processing and that most of the so-called chemical preservatives were supposed to have been harmful to health, caused them to be banned. Whether they were actually deleterious to health is a matter over which there has been much debate. However, the fact that they are not needed and that the consumer's welfare is paramount, justifies their prohibition.

Control of such substances which have become known as "chemical preservatives" rests on "An Act to Prohibit the movement in interstate commerce of adulterated and misbranded food, drugs, devices, and cosmetics, and for other purposes," otherwise known as the Food, Drug, and Cosmetic Act of 1938. The sections of this act which would affect so-called chemical preservatives are as follows:

"Sec. 402—A food shall be deemed to be adulterated—(a) (2) if it bears or contains any added poisonous or added deleterious substance which is unsafe within the meaning of section 406;

"Sec. 406 (a)—Any poisonous or deleterious substance added to any food, except where such substance is required in the production thereof or cannot be avoided by good manufacturing practice shall be deemed to be unsafe for purposes of the application of clause (2) of section 402."

Chemical preservatives would also be affected by part of the definition of misbranding:

"Sec. 403—A food shall be deemed to be misbranded (k) if it bears or contains any artificial flavoring, artificial coloring, or chemical preservative, unless it bears labeling stating that fact:"

Owing to the fact that strict adherence to these edicts is practically impossible with certain foods the administrator of the Food and Drug Administration of the Federal Security Agency under whose jurisdiction enforcement of the act now rests, may at times permit deviations. For instance under Sec. 406, quoted above, it is stated:

"But when such substance is so required or cannot be so avoided the Secretary shall promulgate regulations limiting the quantity therein or thereon to such extent as he finds necessary for the protection of public health, and any quantity exceeding the limits so fixed shall also be deemed to be unsafe for purposes of the application of clause (2) of section 402 (a)." (See Sec. 402a on page 52.)

This clause provides for so-called *tolerances* for undesirable ingredients in foods. Thus tolerances have been established for lead and arsenic contents of sprayed fruits and vegetables and for mold content of certain tomato products.

The administrator is also empowered to make exceptions in enforcement of Sec. 403 (k) quoted above:

"That to the extent that compliance with the requirements of this paragraph is impracticable, exemptions shall be established by regulations promulgated by the Secretary."

These last-mentioned provisions make it possible to debate whether the administrator should make these exceptions.

Interest by both the general public and food-control officials has been focused on "so-called chemical preservatives" for some 40 years.

By Act of Congress, in 1903, the United States Department of Agriculture was directed to investigate preservatives in food and their effect upon digestion and health. The Act was stated as follows: "To investigate the character of proposed food preservatives and coloring matters, to determine their relation to digestion and to health, and to establish principles which should guide their use."

The Food and Drug Act of 1906 was in part, the result of this effort. In this Act it is stated that food shall be considered to be adulterated if it contains any added poisonous or other added deleterious ingredient, which may render such article injurious to health. It became necessary, then, to determine the possible poisonous properties of chemical preservatives. This was not an easy matter, as indicated by contradictory reports which were published.

The conclusions reached in some of the investigations are interesting. In some cases the decisions have been contested and the field has been left in a controversial state. Barnard⁷ stated that a suitable food preservative should have the following characteristics:

1. It must not make possible the employment of careless and imperfect methods of manufacture.
2. It must not, under any reasonable conditions, injure the health of the consumer.
3. It must not allow the use of unfit raw material.

7. Barnard. 1911. Chem. Eng. 12, 104.

4. It must be nonirritant.
5. It must not retard the action of the digestive enzymes.
6. It must be efficient in its preservative action.
7. It must have no tendency to decompose in the body into poisonous substances, the dose of which is smaller than its own.
8. Easily detected for control work.

It is obvious that such requirements would be found with difficulty in one chemical substance.

What is a "Chemical Preservative?" Few food-control officials or technologists have tried to define the term although it is used especially by the former. It is our purpose to analyze in this paragraph what Congress meant by the statement, in Sec. 403 (k) of the Food, Drug, and Cosmetic Act of 1938, that a food shall be deemed to be misbranded if it contains a "chemical preservative" unless its label states that fact.

The term "chemical preservative" grew out of the controversies incident to the so-called "pure-food movement" so ardently sponsored by Dr. Harvey Wiley. It was applied to several chemical substances which are discussed in the next few pages, i.e., sodium benzoate, formaldehyde, salicylic acid, sulfites, and boric acid. These are the substances to which the term "chemical preservatives" should be applied for they brought it into being. The term should not be applied to all chemical substances which are added for one purpose or another to food substances to prevent various types of deterioration unless these newer substances have about the same characteristics. When the term was first introduced it was applied to substances which had such marked characteristics that they were sharply set apart as follows:

1. They were foreign to the human body—were not found in it and were probably not formed in it during digestion.
2. The body had to have some definite method of detoxifying and eliminating them.
3. They were used to conceal inferiority in raw materials and avoidable difficulties in processing.
4. They were not normal constituents of foods.
5. Where used in food they stigmatized the food on account of the evil connotation which the term had.

This problem simmers down to the meaning of words when they were first coined and used. Laws and rulings must be construed in light of new and changing conditions and advances in science. The courts, for instance, have said that the language of legislative enactments should be construed in accordance with its meaning at the time used rather than by a meaning attributed to it many years later.

In *People v. Barnett*, 319. Ill. 403, the court said:

"... The true rule is that statutes are to be construed as they were intended to be understood when they were passed. Statutes are to be read in light of attendant conditions and that state of law existent at the time of their enactment. The words of the statute must be taken in the sense in which they were understood at the time the statute was enacted. . . .

"... The legislative intent that controls in the construction of the statute has reference to the legislature which passed the given act. . . . In interpreting a statute the question is what the words meant to those using them. . . ."

The term preservative is so general and indefinite that much trouble is experienced in using it. The British Food and Drug Act of 1928 defined it as follows:

“‘Preservative’ means any substance which is capable of inhibiting, retarding, or arresting the process of fermentation, acidification, or other decomposition of food or of masking any of the evidences of any such process or of neutralizing the acid generated by any such process; but does not include common salt (sodium chloride), saltpeter, (sodium or potassium nitrate), sugars, acetic acid, or vinegar, alcohol or potable spirits, spices, essential oils or any substance added to food by the process of curing known as smoking.”

The committee appointed by the Minister of Health of Great Britain to study the use of preservatives and coloring matters in 1923, found that it was undesirable to add to foods any material not of the nature, substance, and quality of food and recommended that preservatives should be prohibited in all articles of food and drink offered or exposed for sale, with a few exceptions. The term preservative, it was stipulated, was not to include salt, saltpeter, sugar, vinegar, acetic acid, alcohol, spices, or the agents introduced into food by the process of curing known as smoking. It was further stated that preservatives were used in a haphazard way. Three groups were recognized:

1. Formaldehyde and its derivatives; fluorides.
2. (Not so desirable.) Boric acid and salicylic acid and their salts.
3. (Least harmful.) Benzoic acid and sulfurous acid and their salts.

The committee stated that if preservatives were necessary only those in Group 3 should be permitted. This conclusion was of great importance because those in Group 2 were being used at the time of the investigation. This investigation resulted in the permitted use of two preservatives—benzoic and sulfurous acids and their salts. They were to be allowed in sausages, wines, dried fruit, fruit pulp, beer, cider, cordials, and fruit juices. It was suggested that sulfur dioxide be used in all of these foods in certain quantities. The committee further stated that presence of a preservative should be stated on the label. Thus the recommendations placed the use of preservatives in foods in Great Britain on the same bases as in the United States. British manufacturers were given two years to arrange their affairs under the new order. The conditions under the old order were reported in part by McFadden.⁸ As would be expected, this order aroused considerable discussion, most of which centered about boric acid.

Another attempt at defining the term “chemical preservative” appears in an “advisory definition” attached to Sec. 403 (k) (a) (3) of the U. S. Food, Drug, and Cosmetic Act of 1938.

“The term ‘chemical preservative’ means any chemical which, when added to food, tends to prevent or retard deterioration thereof; but does not include common salt, sugars, vinegars, spices, or oils extracted from spices, or substances added to food by direct exposure thereof to wood smoke.”

This definition does not appear in the Food, Drug, and Cosmetic Act approved June 25, 1938, and was not, therefore, passed by Congress. It

8. McFadden. 1908. Local Govt. Bd., Gt. Brit., Rev. in Exp. Sta. Rec. 21 (1909), 164.

is a suggestion issued by the Food and Drug Administration as an aid in enforcing the act. It was apparently based on the definition which appears in the British Food and Drug Act of 1928. If this is true, some modifications were made, for the American version makes no exception of "alcohol or potable spirits" and saltpeter.

Mere definition of the term "chemical preservative" does not prove whether a substance is one or not. Actually this can be determined only by long experiments if it can ever be satisfactorily proved. These must involve use of various microorganisms, or various strains of the same organism, in varying numbers under varying conditions, and finally actual use under practical conditions with thorough laboratory examination.

Must the term "chemical preservative" be limited only to those substances which interfere with microbial deterioration? Such a distinction should probably not be made. If a definition for the term "chemical preservative" must be established it should be so worded that any chemical substance, irrespective of its nature or the reasons for which it is added to food, is included. No exceptions should be made for any substance. Such exceptions are arbitrary and become subject to discussion and controversy.

Reckless addition of all sorts of chemical substances to food is to be deplored. They should be permitted only if they are harmless and improve the food.

On the other hand, refusal on the part of food-control officials to permit addition of a harmless chemical substance to food "where such substance is required in the production thereof or cannot be avoided in good manufacturing practice" and to accord it the dignity of an "optional ingredient" is equally to be deplored. Research in the food industries has given us in the United States the finest foods of any nation in the world and technology has played a great role, especially chemistry and bacteriology. Any such chemical substance accepted as an "optional ingredient" should have the following general properties:

1. It should have some definite role in the food.
2. It should be harmless to health—not deleterious.
3. It should not conceal inferiority or faulty processing.
4. It should preferably be a substance normally in food or formed in foods by accepted processes, such as fermentation.

Several such substances have already been accepted as "optional ingredients" and are not required to be listed on labels. Some of these are the following:

Disodium phosphate or sodium citrate, or both, or calcium chloride in evaporated milk as a stabilizer.

Sodium carbonate or hydroxide as a neutralizer in cream.

Brine acidified with citric acid as a medium into which crab meat may be dipped to prevent discoloration before canning.

Calcium chloride in canned tomatoes to prevent physical deterioration.

Vinegar and various inorganic salts in bread.

Citric acid in canned artichokes and mushrooms.

Closely related to "chemical preservatives" are so-called "inhibitors." These are agents which act temporarily for a few days or so, whose action

is soon gone, and deterioration continues. Are they preservatives? Probably not, for two reasons: (1) they do not preserve over a sufficiently long time; and (2) they are not in the same category with those substances from which the term originated and which Congress had in mind when it passed the Food and Drug Act of 1906.

BORIC ACID (BORACIC ACID)

This compound has been one of the last to be placed on the prohibited list of preservatives for foods by most nations. It has had a few proponents for use in certain foods, but in later years the opponents have prevailed. There is probably no valid reason why it should be used. Boron compounds have been prohibited for a number of years in France, Germany, Holland, Italy, Spain, the United States, and since 1927 in Great Britain. In the United States use of boron compounds in meats is prohibited by the Bureau of Animal Industry Order 211, Regulation 18, Section 6, Paragraph I.

Before being placed on the prohibited list in England, boric acid was largely used in butter, cream, margarine, imported liquid eggs, sausages, potted meats, potted fish, and some beverages. It was also permitted for packing hams and bacon for import into England.⁹ When so used it was ordinarily dusted over these products. According to this practice large amounts were frequently present. Thus 175, 140, and 110 grains per pound have been found in margarine, butter, and bacon, respectively. Usually, however, the quantity did not exceed and rarely amounted to 35 grains. One trade representative told the committee that 52 grains of boric acid per pound were necessary for his product. When boric acid was permitted, the government had little control over the amounts. In 1917, an order¹⁰ was issued that no more than .4 per cent should be used in cream and that cream so treated should be sold as preserved cream. Robertson¹¹ cited experiments and authorities to show that small amounts (.2 per cent) added to milk were not deleterious to human health. Therefore, he believed that its addition to milk as a preservative should be allowed, because it would help avoid the use of milk undergoing decomposition. The enforcements of the Food and Drugs (Adulteration) Act of 1928 in England developed considerable opinion against the prohibition of the use of boron compounds. Many protests were made against the Act. The arguments, in general, were that boric acid was needed as a preservative in order to prevent decomposition and that refrigeration had not been developed to such an extent that it could take the place of boric acid. Many eminent medical men and men of science in England declared themselves against the prohibition.¹² On the other hand, those who favored it argued that the food preservatives then in use were drugs and that pharmacopoeias laid down limits for use in prescriptions. There was justification, therefore, in the prohibition.

12. J. Amer. Med. Assoc. 1925. 85, 1148.

It is generally accepted that boric acid is poisonous when taken in sufficiently large amounts. Furthermore, some of those who participated in the boric acid controversy in Great Britain after 1927, believed that small amounts of foods consumed over a long period of time might cause diseases of the kidney. Wiley¹³ stated that boric acid or borax, when administered in small doses for a long period or in large quantities for a short period, created disturbances of appetite, digestion, and health. He, therefore, believed that it should be absolutely prohibited in foods. Harrington¹⁴ and Kister¹⁵ also reported that boric acid was harmful.

Several instances have been recorded of the presence of boric acid in foods. A medical officer in London found sponge cake on the market which contained 35 grains of boric acid per pound. The source was found to be liquid eggs which had been imported from China. Dudding¹⁶ attributed illness among soldiers to boric acid in sausage (800 grams per pound). Levine¹⁷ and Edmondson, Thom, and Giltner¹⁸ discovered a canning powder which contained 95 per cent of boric acid and five per cent of salt. Sea foods have also been reported to contain boric acid. Smelts imported into Great Britain¹⁹ contained it and it was found in imported herrings in sauce and mackerel in oil, in amounts as great as 3,000 p.p.m.

Boric acid at best exerts only a feeble action on bacteria. According to Rost²⁰ large amounts must be used to be effective.

Owing to the emergencies incident to the second World War the Ministry of Food of Great Britain rescinded its former prohibition of the use of boron compounds in the preservation of bacon. According to the order "bacon" included hams and any other part of the carcass of the pig which had been cured in any way but did not include pickled pork. Borax included boric acid and borates. The permission was also extended to the presence of boron compounds in those articles of foods in which bacon and ham are constituents. No mention was made in the order of the maximum amount of boron compounds which would be permitted.²¹

FORMALDEHYDE

Formaldehyde was rather widely used at one time as a preservative in milk. It was placed on the prohibited list after the passage of the Food and Drug Act of 1906. Wiley²² concluded that it deranged metabolism, disturbed the normal functions, and produced irritation and undue stimulation of the secretory activities and, therefore, was never justifiable. While formaldehyde is banned when added as such, it is not prohibited when added in some other ways. Recent work on smoking of

meats and fish has revealed the presence of considerable amounts in smoke and smoked products. In the definition of a preservative in the Food and Drug Act of 1928 in Great Britain, it is specifically stated that products added to foods by the process of curing known as smoking, shall not be considered preservatives. Even though formaldehyde has been on the prohibited list of food preservatives for many years, it is occasionally used by unscrupulous and ignorant individuals. The Food and Drug Administration, as late as 1931, seized 143 gallons of cream which had been preserved with formaldehyde.²³

SALICYLIC ACID AND SALICYLATES

Salicylic acid and its salts are prohibited as food preservatives in the United States. Wiley²⁴ stated that while the compounds were harmful and should be prohibited in foods, they were not as harmful as generally believed. Examination of Wiley's report indicates that the results were not as clear-cut as could be desired. While the statements were general, addition of salicylic acid and salicylates to foods was considered to be reprehensible in every respect leading to injury to the consumer, which, though in many cases not easily measured, must finally be productive of great harm.

SULFUROUS ACID AND SULFITES

The primary purpose of sulfur dioxide in dried fruits is to preserve as far as possible the natural color of the fruit. The amount which has to be used, therefore, depends on several different factors. They must not be used in excess of the amounts really needed, conceal inferiority, or endanger the health of the consumer. When used in dried foods, it must be clearly stated on the label. Sulfur compounds may not be added to meat products according to Bureau of Animal Industry Order 211, Regulation 18, Section 6, Paragraph I.

According to Bitting,²⁵ sulfurous acid was used in 1813 by Hildebrand for preserving meats. It did not, however, have wide application. In 1939, Jordan suggested the use of this agent for preserving meat and fish. Wiley²⁶ stated that administration of sulfurous acid in food was objectionable and produced disturbances of metabolic functions and injury to health and digestion.

Sulfur dioxide does not completely sterilize but probably acts as an antiseptic; nor does it affect fermentation to an injurious extent when nitrogenous food is too low.²⁷ Cruess and Berg²⁸ found that 1,500 p.p.m. of sulfites kept grape juice from fermenting for two years and Nichols²⁹ found it impossible to isolate bacteria from sulfured dried fruits which had been present before sulfuring. Molds, however, were isolated from dried apricots containing 315 p.p.m. of sulfur dioxide. Molds were ob-

served growing on dried pears containing 700 p.p.m. of sulfur dioxide. Nichols attributed this to inadequate sulfuring.

Whether a certain amount is excessive or not depends largely on the reasons for using it as well as the actual conditions which obtain when it is used. Since it is used to retain the natural color of dried fruits the amount needed is determined by the degree of natural color desired. Nichols,²⁹ Chace, Church, and Sarber,³⁰ and Nichols and Christie³¹ stated that satisfactory color retention was not consistently attained if the sulfur dioxide content was below 1,000 p.p.m.; 2,000 p.p.m. are usually necessary and in some cases even 3,000 p.p.m. Nichols and Christie observed a distinct loss of sulfur dioxide during storage for six months. Cooking also destroys much of it.

Despite statements of a few investigators to the contrary, sodium sulfite in amounts used in dried fruits, is probably harmless. Flury³² reported it to be so. Nichols referred to unpublished work of the United States Bureau of Chemistry between 1909 and 1914 which indicated the harmlessness of sulfites and to a declaration of the American Medical Association to the same effect.³³ The British tolerance for sulfur dioxide is 2,000 p.p.m. for strawberries and raspberries and 1,500 p.p.m. for other fruits (Atkinson³⁴).

Sulfur dioxide is also used as a preservative for fruits during shipment because they may be sent without refrigeration. The preservative was found by Atkinson³⁴ to be effective up to two years and to be easily removed.

SODIUM BENZOATE

This is the only chemical preservative which is allowed in the United States. One of the most interesting controversies, in which eminent chemists and physiologists of the day participated, was waged over its use.

Sodium benzoate is not an active preservation agent. Lucas³⁵ reported that it preserved strong acid fruits, but that cider with .1 per cent of sodium benzoate developed mold. Barnard,³⁶ Herter,³⁷ Held,³⁸ and Tanner and Strauch³⁹ all showed the weak action of this compound on bacteria. Held observed a greater effect than the others. Lagoni⁴⁰ recognized a bacteriostatic action of benzoic acid.

Passage of the Food and Drug Act in 1906, in which it was stated that food was adulterated if "it contained any added poisonous or other added deleterious ingredient which may render such article injurious to health," compelled investigations to determine whether sodium benzoate came within these limits. Wiley, then Chief of the U. S. Bureau of Chem-

istry, became an unalterable foe of the compound and remained so until his death.

As a result of the Act of Congress, 1903, Wiley²² and his collaborators conducted an extensive investigation, all of the results of which need not be reported here. They consisted, however, in the administration of benzoic acid and benzoates to a squad of normal, healthy human beings. They concluded that administration of benzoic acid,* either as such or as sodium benzoate, was highly objectionable and produced a serious disturbance of the metabolic functions, attended with injury to digestion and health. This statement covers the conclusion with sufficient completeness.

The group of men to whom Wiley fed sodium benzoate was called a "poison squad," a name certain to attract the attention of the public, and by implication to suggest the harmfulness of the preservative under study. The question was not settled by Wiley's conclusions, for demands were made that unbiased investigations be made. Consequently, former President Theodore Roosevelt appointed a Referee Board of Consulting Scientific Experts, to study the question. This board, which consisted of eminent physiological chemists of the day, concluded that sodium benzoate in small doses (under .5 mg. per day), mixed with food was without deleterious or poisonous effect, and was not injurious to health. In large doses (up to four grams per day), mixed with food, it did not exert a deleterious effect. Further review of conclusions would only amplify what has just been stated, and would add nothing new. These conclusions of the Referee Board were the reverse of those reached by Wiley. Consequently, the Department of Agriculture permitted the use of sodium benzoate as a preservative in foods.

Food Inspection Decision No. 76 issued July 13, 1907, forbade the use of certain preservatives in foods under Section 7 of the Food and Drugs Act of June 30, 1906. Sodium benzoate was reluctantly permitted until more information could be secured. Food Inspection Decision No. 89, issued March 5, 1908, pending determination by the Referee Board, read as follows:

"Benzoate of soda, in quantities not exceeding one-tenth of one per cent may be added to those foods in which generally heretofore it has been used. The addition of benzoate of soda shall be plainly stated upon the label of each package of such food."

After the Referee Board, composed of Dr. Ira Remsen, Dr. R. H. Chittenden, Dr. J. H. Long, Dr. A. Taylor, Dr. C. A. Herter, and Otto Folin, reported on their extensive investigations, Food Inspection Decision No. 104, issued March 3, 1909, read as follows:

"The Board reports, as a result of three extensive and exhaustive investigations, that benzoate of soda mixed with food is not deleterious or poisonous, and is not injurious to health. The summary of the report of the Referee Board is published herewith.

"It having been determined that benzoate of soda mixed with food is not deleterious or poisonous, and is not injurious to health, no objection will be raised under the

* Other chemical compounds which have at times been used in food preservation, but which have since been placed on the prohibited list, will not be discussed in this book. They will be considered in the companion volume on "Food Poisoning and Food Infection," the second edition of which is in preparation.

Food and Drug Act to the use in food of benzoate of soda, provided that each container is plainly labeled to show the presence and amount of benzoate of soda.

"Food Inspection Decisions 76 and 89 are amended accordingly."

While Wiley may have been too arbitrary with respect to the harmfulness of sodium benzoate, his great contribution to the pure-food movement must not be overlooked. This came at a time when it was sorely needed. Few can deny the validity of his argument that if sound raw materials were preserved by adequate procedures, a preservative would not be needed. This position has been vindicated by experience. Sodium benzoate is not now used to any extent if at all.

Acidity of food apparently has considerable effect on the activity of sodium benzoate according to results of experiments by Cruess and his colleagues, Richert and Irish,⁴¹ who used various microorganisms and several different preservatives. Concentrations of all of the latter except sodium chloride and formaldehyde required to prevent growth of the organisms were much greater at a pH from 5 to 5.9 than at a pH from 2 to 4.5. At pH 7, as much as 300 times the concentration of certain preservatives was required to prevent growth as at pH 3 to 3.5.

At neutrality, approximately four per cent of sodium benzoate was required to prevent growth of most of the fermentation organisms studied; whereas at pH 2.3 to 2.4, only .02 to .03 per cent was required, and at pH 3.5 to 4 (the range for most fruit juices) only .06 to 1.10 per cent. The nonacid-tolerant organisms (*Escherichia coli*, *Bacillus subtilis*, *Clostridium sporogenes*, *Clostridium botulinum*) did not grow at pH values below 4; nevertheless, the inhibiting action of sodium benzoate depended on hydrogen-ion concentration. A *Penicillium* was found growing profusely, although not sporulating, in a 10-per cent sodium benzoate solution near neutrality. Their results showed that salts of these weak acids exert relatively slight toxic action on microorganisms, near neutrality, but exert their maximum effect in the moderately strong acid range. Toxicity was believed to depend on concentration of undissociated acid, rather than on that of their anions. In asparagus juice, *Clostridium botulinum* grew and formed toxin at pH 7.4 with .8 gram of sodium benzoate per 100 ml., but failed to grow or form toxin at pH 4.7 with .1 gram. Observations at other pH values confirmed the theory that hydrogen-ion concentration is of primary importance in preventing growth of this organism; it was therefore believed to be dangerous to attempt to preserve nonacid foods with sodium benzoate. Near neutrality, two per cent of benzoate failed to prevent spoilage of ripe olives, avocado pulp, melon preserves, maraschino-type grapes, prune pulp, carbonated beverages, asparagus, string beans, green peas, and artichokes packed in dilute brines or sirups; whereas at pH 4 (or lower) spoilage was prevented by .1 per cent or less of the preservative. At pH values of 4 to 7 the concentrations to prevent spoilage were intermediate between these extremes. Schmidt-Lange⁴² also

found sodium benzoate to inhibit *Clostridium botulinum*. The influence of hydrogen-ion concentration was also observed by Goshorn, Degering, and Tetrault.⁴³

Besides chemically known substances just discussed, there are others such as those found in wood smoke used in meats and other foods. Pettet⁴⁴ found several constituents in wood smoke which might have significance in food preservation. Among these were formaldehyde, higher aldehydes, formic acid, acetic acid, and higher acids. Tar amounted to 12 per cent of dry wood. Such a mixture should be quite bactericidal.

ACIDS AND HYDROGEN-ION CONCENTRATION

The hydrogen-ion concentration of food influences its deterioration by microorganisms. This is discussed at various places in this book. Some study has been given to the effect on microorganisms of the acids themselves. Kruger⁴⁵ added organic acids to nutrient broth to produce final concentrations of 1 to 10 to 1 to 1,000,000, after which they were inoculated with pure cultures. Subcultures were made during incubation. *Escherichia coli* was most resistant to lactic acid, withstanding a concentration of 1 to 100 for four hours. *Salmonella enteritidis* was least resistant withstanding a concentration of 1 to 100 for only two hours. *Pseudomonas aeruginosa*, *Proteus vulgaris*, and *Staphylococcus aureus* were approximately equal in resistance to lactic acid but were less so than *Escherichia coli*. Differences were observed among all strains of a species. The bactericidal effect of the organic acids tested was not attributable to the hydrogen-ion concentration but to the chemical character of the acid. Lactic acid showed the greatest activity, its inhibiting ability being influenced largely by the time of exposure. Levine and Fellers⁴⁶ found that acetic acid in nutrient broth inhibited various organisms related to food spoilage. The organisms which they used did not grow in broth adjusted to a pH of 4.9 with acetic acid. *Saccharomyces ellipsoideus* did not grow at pH of 3.9 and *Aspergillus niger* was inhibited at pH 4.1. An increase in the hydrogen-ion concentration resulted in a decrease in thermal death time. Reduction in the lethal temperature was more marked in the case of *Bacillus mesentericus* and *Bacillus cereus* than with the non-spore forming organisms. Thermal death times of the yeast and mold were not altered by addition of small amounts of acetic acid. Acetic acid was more toxic than either lactic or hydrochloric acids for *Salmonella aertrycke*, *Saccharomyces cerevisiae*, and *Aspergillus niger*. Levine and Fellers did not attribute the action of these acids to hydrogen ions alone but in part to undissociated acetic acid molecules. Tetsumoto⁴⁷ also reported a strong sterilizing power of vinegar toward *Eberthella typhosa* and *Vibrio comma*.

Reaction of foods has been found to be of primary importance with respect to development of *Clostridium botulinum*. This organism does not

develop in foods more acid than pH 4.5. When foods originally more acid than this have caused botulism, presence of other bacteria have been shown which have destroyed some of the acid. Therefore, this critical hydrogen-ion concentration (pH 4.5) probably cannot apply to unprocessed foods with a heterogeneous flora of microorganisms, or processed foods in which all of the microorganisms have not been destroyed.

CONCENTRATED SOLUTIONS

Concentrated solutions of salts, sugars, or mixtures of them are used in preservation of certain foods to repress development of microorganisms. Salt, for instance, is used in curing meats, in cucumber pickles, and in sauerkraut fermentations. In these cases the microbial flora is greatly simplified and reduced to types which can endure large concentrations of salt.

Concentrated Sugar Solutions. Sirups, or solutions of sugar in water, are used in preservation of fruits. They are used more for their effect on flavor than for their ability to harm bacteria. Other methods, such as heating to high temperatures, must be used for ridding fruits in sirup of microorganisms. Sirups alone cannot be used because some microorganisms are able to remain viable in heavy sirups. Honey may contain microorganisms which are quite tolerant to high sugar concentration and even grow. According to Grove⁴⁸ yeasts and molds cannot ordinarily develop in sugar solutions of over 50 per cent. Penicillium was checked at 65 per cent, but after a month, feeble growth was noticed at even 70 per cent. Heidemann, in the author's laboratory, secured results with yeasts which agreed with those of Grove.

Fruits preserved with sugar are usually heated for final destruction of microorganisms. Rahn⁴⁹ showed that heavy sirups may protect microorganisms from heat since pure cultures of yeasts showed longer death times when heated in sirups. This subject is dealt with a little later in this chapter and in several others.

Molds cause considerable deterioration of fruit products containing large amounts of sugar. Macara⁵⁰ found that at relative humidities below 82 per cent, fruit jams containing from 70 to 72 per cent solids will prevent germination of mold spores. He said the osmotic pressure of the jam must equal or exceed that of the spores if mold growth is to be prevented. Jams stored in relative humidities in excess of 82 per cent will absorb moisture. Such moisture may enable spoilage to start at least on the surface.

Occasionally high sugar concentrations alone are suggested for fruit preservation. Nepomniashcha and Liberman,⁵¹ for instance, reported preservation of mixed prunes with 50 to 65 per cent of sugar without heat treatment. After sealing in tins they were reported to have kept for 19 months without swelling. Periodic microbiological examinations did not

reveal any coliform bacteria, anaerobes, or yeasts. The flora consisted exclusively of sporeformers. They suggested that this method might be used for large-scale preservation of fruits. Whether such a method could be used with good results would depend on the bacterial load present, the amount of acid, and other factors. It should not be attempted in the United States for too many microorganisms would develop, as shown by Andreicha,⁵² among others. Neither the highest sugar concentrations used in commercial jams and jellies nor an atmosphere of carbon dioxide approaching 100 per cent alone, suppressed development of common molds; combined action, however, of these two preserving agents was successful. An atmosphere containing 10 per cent of carbon dioxide prevented development of *Aspergillus repens*, *Penicillium areuarum*, and *Penicillium glaucum* on 60 per cent glucose broth. Lower sugar concentrations required higher concentrations of carbon dioxide. Further work on this question is discussed in Chapter 14.

Microorganisms in Sugar. The microbial content of sugar has been studied for several reasons. It was necessary to have information on this subject to know the effect of various processes used in its manufacture on microorganisms, to learn the origin of various species which deteriorate sugar during storage, and to determine whether microorganisms may be present which may cause undue spoilage when the sugar is added to other foods. Since these subjects are discussed in a later chapter, they will not be considered here.

Effect of Concentrated Salt Solutions on Microorganisms. Concentrated solutions are widely used for preservation of meats and some vegetables. The bacteria responsible for desirable fermentations in meat curing and sauerkraut fermentation are relatively salt tolerant. The action of salt in food preservation is generally attributed to plasmolysis. Although the results of Lindet's⁵³ experiments seem to confirm this opinion, it is doubtful whether the explanation is so simple. Fischer stated that plasmolysis lasted only for a certain length of time, usually a few hours, and that not all bacterial cells would be affected. Rockwell and Ebertz⁵⁴ believed that at least five factors were involved in the detrimental action of salt on bacteria: dehydration, direct effect of the chloride ion, removal of oxygen, sensitization against carbon dioxide, and interference with rapid action of proteolytic enzymes. Pettersson⁵⁵ observed a marked simplification of the flora with increasing salt concentration. In low concentration the flora was heterogeneous; the rods were eliminated between 12 and 15 per cent; wild yeasts dominated the flora at 25 per cent. LeFevre and Round⁵⁶ reported bacteria which were said to require 25 per cent of salt to grow. Others who made significant contributions are Stadler,⁵⁷ de Freytag,⁵⁸

Lewandowsky,⁵⁹ Weichel,⁶⁰ and Serkowski and Tomczak.⁶¹ The effect of salt seems to be influenced greatly by the substrate to which it is added and the microorganisms which are present. While it is generally stated that 10 per cent of salt will inhibit *Clostridium botulinum*, some strains are apparently able to endure greater amounts.

Less information is available on the effect of salt solutions on yeasts and molds. The latter are inhibited by 20 to 30 per cent solutions although slight growth may occur after long times. Wehmer⁶² isolated a yeast from herring brine which was inhibited by 15 per cent of salt. Speakman, Gee, and Luck⁶³ reported that solutions with 10 per cent of salt were fermented by *Saccharomyces cerevisiae*. 'Above this concentration fermentation became slower and slower. Other yeasts are salt resistant as indicated by Karaffa-Korbitt.⁶⁴ According to Thom,⁶⁵ Penicillia are inhibited by 15 per cent of salt.

Various microorganisms in addition to bacteria may persist in strong brines. Baas-Becking⁶⁶ reported several species of protozoa as well as several species of higher bacteria. Both halophilic and non-halophilic species were isolated from brines by Hof.⁶⁷ Microorganisms from saltless sources were less tolerant to salt as a rule. However, some halophilic species isolated from soil were believed to have originated from normal soil bacteria.

Halophilic bacteria are not restricted in habitat to salt or concentrated brines but may be cultivated from other sources. Stuart⁶⁸ found them widely distributed.

Microorganisms in Salt. A diverse flora would not be expected in salt produced and handled under good conditions. Large numbers, however, have been obtained in some cases. Pierce⁶⁹ who examined the flora of brines of salt works in the San Francisco Bay region for three years, found that the concentration of the brine was the most important factor relating to numbers of microorganisms found. All of the species which he isolated were saprophytic. Wolff⁷⁰ urged that salt used in the dairy industry be examined bacteriologically. He found bacteria, yeasts, and molds to be common. In one case the brine contained 315,000 bacteria per ml., some of which would have been troublesome in butter. Rappin and Weigmann⁷¹ published similar conclusions. In a later publication, Rappin⁷² reported a salt with 1,300 to 38,000 bacteria and 100 to 400 fungi per

gram. In America, Yesair⁷³ recommended that the bacteriological condition of salt be considered and understood by food preservers. He found putrefactive anaerobic bacteria in some salts and advised against the use of such salt in the meat industry. Rahn⁷⁴ has also pointed out the need for handling salt properly in food-preservation establishments. He called attention to the ease with which it may be contaminated and the evil consequences which may result. In this connection Baas-Becking⁷⁵ discussed early methods of salt manufacture and a few microbiological problems related thereto.

LOW TEMPERATURES

The inhibitive effects of low temperatures on bacterial development in foods are pointed out at various places in this book. Cold storage and refrigeration are important for preservation of such foods as meats, milk, and eggs. Variations of only a few degrees are of great significance. Refrigeration above freezing cannot be relied upon to hold foods indefinitely. As long as moisture is available for bacterial development, foods will undergo slow deterioration. Most bacteria and parasites survive freezing although their numbers may be markedly reduced. *Trichinella spiralis* in pork is killed by freezing at $-15^{\circ}\text{C}.$ ($5^{\circ}\text{F}.$) for 24 to 36 hours. Freedom from these parasites is insured by holding them for not less than 20 days at this temperature. This allows an ample margin of safety.

The Committee on Foods of the American Public Health Association has on several occasions discussed the health aspects of refrigeration.⁷⁶ The factors involved in successful refrigeration, according to Ferguson,⁷⁷ are, in general, low temperatures, correct humidity, proper atmosphere, controlled odors, and sound foodstuffs in the beginning. Prescott and Tanner⁷⁸ also discussed the health aspects of foods preserved by low temperatures.

Introduction of the electric refrigerator into the home was probably one of the most significant events which has happened in food preservation in several decades. It is now possible to maintain constant temperatures which are known to keep food in a satisfactory manner. These instruments have not only made it possible to preserve food better but have added much to the convenience and pleasure of living, especially in warm climates. Cold is the most satisfactory agent for preservation of foods for short periods of time. Refrigeration preserves large amounts of food during shipment. The committee appointed by the Ministry of Health of Great Britain to investigate the use of chemical preservatives in food advised that refrigeration be employed as much as possible.

Introduction of "dry ice," solid carbon dioxide, into food preservation has also been a significant event. It is now being used for shipment of meat, yeast, fish, and other foods. Very low temperatures are obtained.

Killeffer⁷⁹ stated that the actual temperature of a block of "dry ice" is not higher than $-74^{\circ}\text{C}.$ ($-101.2^{\circ}\text{F}.$) and may be as low as $-109^{\circ}\text{C}.$ ($-165^{\circ}\text{F}.$). Its cooling value is twice that of ice. According to Killeffer, carbon dioxide itself exercises a preservative action on certain food products. He stated that meat and fish can be kept fresh longer when refrigerated in carbon dioxide atmosphere than in air. Furthermore, it was also shown that carbon dioxide in culture media repressed, if it did not kill, common bacteria. It is a controversial question whether carbon dioxide has any pronounced effect on keeping quality.

In some cases, it has been necessary to determine what temperatures of storage constitute effective refrigeration. Such is the case for *Clostridium botulinum*. Tanner and Oglesby⁸⁰ and Tanner, Beamer, and Rickher⁸¹ found that $10^{\circ}\text{C}.$ ($50^{\circ}\text{F}.$) prevented development of and toxin formation by this organism for a considerable period of time. Growth occurred and toxin was produced within a few days at $20^{\circ}\text{C}.$ ($68^{\circ}\text{F}.$) when either vegetative cells or spores were inoculated, and at $15^{\circ}\text{C}.$ ($59^{\circ}\text{F}.$) when vegetative cells were inoculated. At $15^{\circ}\text{C}.$ ($59^{\circ}\text{F}.$) toxin production by detoxified spores rarely occurred. At $10^{\circ}\text{C}.$ ($50^{\circ}\text{F}.$) growth of vegetative cells, if their appearance in eight cultures is taken as being normal for that temperature and not as the result of the short exposure to higher temperature, occurred only after 27 days. Growth of detoxified spores did not occur in 47 days, and no growth occurred at $5^{\circ}\text{C}.$ ($41^{\circ}\text{F}.$) in any medium, though incubation was continued to 108 days in some cases. This would seem to indicate that foods stored at room temperature or under only slight refrigeration may become dangerous fairly rapidly, but when kept at less than $10^{\circ}\text{C}.$ ($50^{\circ}\text{F}.$) will remain safe for a considerable length of time.

The relation of time of appearance of growth to development of toxin was shown with two strains at $20^{\circ}\text{C}.$ ($68^{\circ}\text{F}.$) and one strain at $15^{\circ}\text{C}.$ ($59^{\circ}\text{F}.$). In two cases the filtrate injected as soon as a heavy turbidity of growth appeared required two days to cause the death of a mouse. When the same cultures were injected after one more day of incubation, death of the mouse occurred in one day. In the case of one culture results were similar except that two days intervened between two injections. Tanner and Oglesby found appreciable difference among strains of *Clostridium botulinum* in temperature relations. Results of the investigation by Tanner, Beamer, and Rickher⁸¹ with food products confirmed the work just reported. The same problem was studied by Prescott and Geer⁸² for other bacteria. With *Clostridium botulinum*, refrigeration of properly prepared foods at temperatures below $10^{\circ}\text{C}.$ ($50^{\circ}\text{F}.$) prevented formation of toxins for extended but undetermined periods. Spoilage of food by other types of bacteria can, however, take place at $50^{\circ}\text{F}.$ In food-poisoning, such as that caused by the Salmonella group, limitation of numbers

79. Killeffer. 1930. Ind. Eng. Chem. 22, 140-143.

80. Tanner and Oglesby. 1936. Food Research 1, 481-494.

of the organisms to a minimum is the essential result to be attained. For these organisms refrigeration at 10°C.(50°F.) is not sufficiently effective, and if security against growth is to be attained, it is necessary to maintain the foods at temperatures not above 3.9°C.(39°F.).

When large numbers of bacterial cells belonging to different types of milk streptococci were added to milk by Foter and Rahn⁸³ and incubated at 0 to 2° C. (32 to 35.6° F.), lactic acid was produced. Fermentation occurred slowly and ceased at low acidity. It did not appear to depend entirely upon growth, though it was more marked with such organisms as *Streptococcus fecalis*, *Streptococcus cremoris*, and *Streptococcus liquefaciens* which were able to grow at 0°C.(32°F.) than with organisms like *Streptococcus lactis* and *Lactobacillus acidophilus* which failed to do so. Growth curves showed that *Streptococcus lactis* and *Lactobacillus acidophilus* both multiplied slowly at 5°C.(41°F.). The shortest generation times occurred with *Streptococcus fecalis* at about 37°C.(98.6°F.), with *Streptococcus lactis* at about 30°C.(86°F.) and with *Lactobacillus acidophilus* at about 40°C.(104°F.). The greatest bacterial crops were yielded between the optimum and 10° below optimum.

The practical effects of low temperatures are also indicated in other ways. Barker and Grove⁸⁴ stored cider in bottles for four or five months. Part was held in cold storage at 1°C.(33.8°F.) and part in cellar storage at about 13 to 16°C.(55.4 to 60.8°F.). That held at 1°C. retained better flavor and color, lost less in acidity and specific gravity, and contained much less deposit of yeast and bacteria than that held at high temperature. The influence of temperature upon autolytic and bacterial decomposition of haddock muscle within the range of 2.2 to —1.1°C.(36 to 30°F.) was followed by Hess⁸⁵ by determining the increase in the amount of volatile basic nitrogen parallel with the increase in the number of bacteria. A mixed flora of bacteria normally occurring on haddock was used for inoculation. The experimental results showed that practically no autolysis took place at these temperatures, and that bacterial decomposition and bacterial growth rate at —1.1°C.(30°F.) is about half that at 2.2°C.(36°F.). The practical application of these findings has been demonstrated to be of economical importance in the holding of fresh fish at —1.1°C.(30°F.) instead of the customary holding in crushed ice at about 2.2°C.(36°F.).

Laboratory tests by Danner⁸⁶ indicated a range of 4.4 to —7.2° C. (40 to 45° F.) as the most efficient food-storage temperature for the home. Foods lost less weight in ice than in electric refrigerators, when stored at the same temperature. Foods in the gas refrigerator lost, in most instances, more weight at corresponding temperatures than in the electric refrigerator. Temperature in ice refrigerators increased with increase in room temperature. Foods spoil more readily with a heavy frost on the cooling

unit. Moran and Pique,⁸⁷ and several others later, advised incorporation of antiseptics in ice to be used for preserving foods.

PRESERVATION OF FOODS BY FREEZING

This method of food preservation has enjoyed wide and rapid expansion in recent years. Development of varieties of fruits and vegetables which, upon thawing, retain their shape and flavor, has placed the industry on a firmer basis, as has availability of freezing-storage display cases for merchandising frozen foods. The nutritional aspects, not to be ignored for any preserved food, are not within the scope of this book. Those who are interested in this subject may consult a review by Rose⁸⁸ and numerous other discussions of a similar nature.

The history of preservation by cold, prior to and since the advent of quick-freezing, has been reviewed by Birdseye and Fitzgerald.⁸⁹ The quick-freezing industry developed slowly and was concerned almost wholly with fish until about 1929, when it was applied to other food products. Laboratory research and commercial applications have made it possible to preserve meats, fish, fruits, and vegetables with little or no loss of natural flavor and color. This industry appears to merit consideration as one of the most important developments of the 20th century. Freezing brings to the consumers foods nearer to their fresh state than any other method of preservation. Frozen foods are probably nearer fresh foods than canned foods and may be better from the nutritional standpoint. So far as bacteriological examination is concerned, frozen foods are in a class by themselves. Enumeration of viable bacteria, according to Sanderson,⁹⁰ as a means of sanitary control, does not solve the problem of pathogenic bacteria. Count of *Escherichia coli* along with the total count, would be better than the total count alone. Whether sufficient work has been done to show the true value of the count is doubtful. If counts are to be used, standards must be set up and standard methods developed to accompany them. Tressler¹⁰³ found a low bacterial count in frozen foods which were prepared from good raw materials.

Fundamental Principles Involved. Thorough freezing of foods involves changes in the state of moisture in the tissue. Slow-freezing yields a product with undesirable characteristics, such as loss of shape after thawing, loss of color, and finally loss of considerable amounts of moisture, spoken of as "drip" in the meat-preservation industry. The problems involved were early studied by Richardson and Scherubel⁹¹ who described separation of water from tissues and its freezing between the muscle fibers. When the meat thawed some of this water was reabsorbed. That which was not was released from the meat as "drip." Since then many investigators have found the freezing process to be much more complicated. Publica-

tions by Stiles,⁹² Diehl,⁹³ and various notes in the annual reports of the Food Investigation Board are concerned with the latest ideas on the subject.

Development of Methods for Freezing Foods. Freezing is a natural phenomenon but apparatus which has been developed for using it under controlled conditions for preservation of foods has greatly influenced the effects it may have on the food. Grayson⁹⁴ stated that there were six fundamental systems for quick-freezing foods:

1. Direct still air—numerous systems
2. Brine immersion—Cook, Kolbe, and Peterson
3. Atomized brine—"Z" system and Bloom system
4. Pressure-plate, direct-expansion, portable freezers (General Food Corp.)
5. Direct, carbon dioxide, instantaneous system—Grayson
6. Direct, high-velocity air with multistage intense refrigeration—Grayson

Direct still air was said to be the oldest method although it did not permit quick-freezing.

Air-frozen, slow-frozen, and sharp-frozen are synonyms for products frozen in modern "sharp-freezers" with a minimum temperature of -23.3 to -26.1°C. (-10 to -15°F.). "Quick-frozen," according to Birdseye,⁹⁵ is used to designate products which have been frozen by direct immersion in a liquid refrigerant, such as sodium chloride brine, or by indirect contact with a cold liquid refrigerant, such as calcium chloride brine. Birdseye attributed the merits of quick-freezing to the size of ice crystals in the cells. During that period in which most of the moisture is being frozen, individual ice crystals are constantly increasing in size. After the temperature has reached -3.9°C. (25°F.) most of the water has frozen and the growth of individual crystals largely ceases. Birdseye characterized the temperature zone from -6°C. (31°F.) to about -3.9°C. (25°F.) as the zone of "maximum crystal formation." Since the size of crystals depends on the time allowed for them to form, it is obvious that the more quickly flesh, for instance, is passed through this zone the smaller the crystals will be in the product. Birdseye stated that in the usual sharp-freezing of fish, much time is allowed for formation of large crystals, some of which are as much as one inch in length. These large crystals rupture the cells and bring about changes which make the flesh more susceptible to attacks of bacteria and to autolysis. Birdseye reported data secured with haddock which showed that the quick-frozen product was superior to the slow-frozen. Apparent difficulties are involved in freezing large particles of food, such as whole quarters of beef. Heat cannot be removed rapidly enough for the meat to freeze quickly.

Not all have accepted this explanation for superiority of "quick-frozen" over "slow-frozen" foods. Taylor,⁹⁶ for instance, does not accept it. He stated that the amount of "drip" from thawed frozen meats bears

no relation to the rapidity of freezing. He furthermore stated that the true explanation of what happens will be found in the province of colloid chemistry rather than mechanics. Those especially interested in the subject should consult the publications of Birdseye, Taylor, and the annual reports of the Food Investigation Board of the Department of Scientific and Industrial Research of Great Britain. This bureau observed that such foods as eggs and meat frozen at $-5^{\circ}\text{C}.$ ($23^{\circ}\text{F}.$) and stored at the same temperature, reverted when thawed to their original state; but if after being frozen at $-5^{\circ}\text{C}.$ ($23^{\circ}\text{F}.$) they are stored at a lower temperature, e.g., $-10^{\circ}\text{C}.$ ($14^{\circ}\text{F}.$), they quickly change.⁹⁷

Preparation of Foods for Freezing. While some foods are ready for freezing as soon as harvested, others must receive special treatment. Certain vegetables are scalded and blanched in order to reduce volume and to remove extraneous matter such as soil. Wiegand⁹⁸ stated that the blanch removes gases, saturates the tissues with water, inactivates enzymes, and minimizes discoloration and deterioration during storage. Packing products in brine or sirup protects them from air and causes them to have a better quality.

One of the most important reasons for treating vegetables and fruits before freezing is to destroy or inactivate their enzymes. Fitzgerald,⁹⁹ Dingle and Berry,¹⁰⁰ Balls and Lineweaver,¹⁰¹ and Joslyn and Marsh¹⁰² have stressed this. Enzymes may not be completely destroyed by blanching. Fitzgerald stated that only those which would spoil the food during storage at $-17.8^{\circ}\text{C}.$ ($0^{\circ}\text{F}.$) for a year or so were inactivated. To destroy all of them the food would have to be virtually cooked and thus harmed for freezing. Enzymatic activity was observed by Dingle and Berry in thawed foods which had been frozen for some time. Thawed tissues which have been frozen disintegrate more rapidly than those which have never been frozen, according to Balls and Lineweaver. Tressler¹⁰³ believed that a low bacterial content in a frozen vegetable indicated good methods of packing and storage and that it had probably not been defrosted since freezing. Absence of enzymes indicates sufficient blanching which will prevent development of off-flavor and loss of color during storage at $-17.8^{\circ}\text{C}.$ ($0^{\circ}\text{F}.$) for a year. Smart and Brunstetter¹⁰⁴ removed samples of lima beans for bacteriological examination at each step in preparation. The first were taken after the beans were shelled and washed. Considerable variation occurred in the microbial content of different lots. Some of this variation was attributed to the weather, for one lot, picked just after a heavy rain, was contaminated with soil which increased the number of bacteria present. Scalding and blanching of the beans at $100^{\circ}\text{C}.$ ($212^{\circ}\text{F}.$)

and 87.8°C.(190°F.) reduced the number of bacteria in proportion to the length of time they were treated. The reduction in count was over 99 per cent. The organisms remaining on the beans were further reduced by freezing and continued storage at -9.4°C.(15°F.). While considerable variation occurred in counts from different cans, the counts were so low that they would be negligible were it not for the fact that partly cooked lima beans form an excellent growth medium. For this reason Smart and Brunstetter advised placing the frozen beans directly in boiling water instead of allowing them to defrost slowly in the refrigerator. This is sound advice from the health viewpoint. Smart and Brunstetter¹⁰⁴ also studied the blanching of spinach and kale. A large variety of bacteria were isolated from fresh, scalded, and frozen spinach and kale. The general bacteria content in both was reduced by over 99 per cent by steam scalding for three to five minutes, and also in most cases further reduced by freezing and storage. There were wide variations in the bacterial counts of the fresh material, but in general the bacterial count of the frozen-packs was low, so with proper care in the handling of spinach and kale and with effective scalding and freezing, high counts should not be encountered. The bacteria present were those ordinarily found in fresh vegetables and do not affect the wholesomeness of the product provided that in cooking the vegetables are placed in boiling water prior to, or immediately after, defrosting.

Effect of Freezing on Bacteria and Related Microorganisms: Introduction of quick-freezing as a method of food preservation revived interest in the general effect of freezing on microorganisms. Many investigations were carried out to determine whether new factors were involved under the conditions which obtain in frozen foods.

Some of the conclusions reached in early investigations of this subject, the literature of which was reviewed by Wallace and Tanner,¹⁰⁵ were based on poor logic. Since a few cells survived in suspensions which were subjected to liquid air temperatures when subcultures were made, it was believed that freezing did not kill microorganisms. These conclusions were based on qualitative work. When quantitative data were collected, however, which involved the actual number of living cells present before and after freezing, a marked death rate was noted. Most of the cells were killed, however, only a small percentage remaining alive. The actual number surviving would be influenced by the number in the initial product. Freezing could not be relied upon to sterilize, for a few bacteria would survive for a long time. Magoon¹⁰⁶ reported that molds, yeast, and bacteria are responsible for spoilage of frozen foods; and that the old belief that freezing destroys them must be revised, for, while the majority of a microbial population is usually killed by freezing temperatures in food products, a small proportion whose vitality is unaffected by subzero temperature survive. Some have been found to resist -252°C.(-421.6°F.) for as long as 10 hours, with no apparent harmful effect. Some are not

105. Wallace and Tanner. 1933. *Fruit Prod. J.* 13, 52-54; 14, 109-113.

106. Magoon. 1932. *Ind. Eng. Chem.* 24, 668-671.

only unharmed by cold but are even able to increase in numbers at temperatures well below $0^{\circ}\text{C}.$ ($32^{\circ}\text{F}.$). The changes brought about in frozen-pack foods differ with the nature of substances and with microorganisms concerned; they are both physical and chemical in nature. Alterations in texture, color, flavor, and healthfulness of the foods result from these microbial activities. When Hess¹⁰⁷ exposed marine bacteria to a moderate freezing temperature, $-16^{\circ}\text{C}.$ ($3.2^{\circ}\text{F}.$), for short periods, sea water offered greater protection than broth media or distilled water. Reduction in number of bacteria was least severe in broth media of optimum salt concentration. During freezing in distilled water, transfer of bacteria from the crystallizing portion of the liquid part occurred. Old strains were more resistant to freezing, and previous cultivation at $-3^{\circ}\text{C}.$ ($26.6^{\circ}\text{F}.$) produced more resistant strains. A higher percentage of cells was killed by freezing at lower freezing temperatures, by prolonged freezing, rapid freezing, and repeated freezing. In truly supercooled sea water higher percentage reduction occurred than in frozen sea water at $-6.5^{\circ}\text{C}.$ ($20.3^{\circ}\text{F}.$) and $-10^{\circ}\text{C}.$ ($14^{\circ}\text{F}.$).

Haines¹⁰⁸ froze suspensions of bacteria in a few seconds at $-70^{\circ}\text{C}.$ ($-94^{\circ}\text{F}.$) in small tubes. The tubes were stored at different temperatures and examined for viable cells at regular intervals. Death was not most rapid at $-20^{\circ}\text{C}.$ ($-4^{\circ}\text{F}.$), the lowest temperature of storage, but in the range of $-1^{\circ}\text{C}.$ ($30.2^{\circ}\text{F}.$) to $-5^{\circ}\text{C}.$ ($23^{\circ}\text{F}.$). Microorganisms were found to vary in their susceptibility to freezing. Spores and *Staphylococcus aureus* were resistant, while *Pseudomonas pyocyaneus* was quite sensitive. Haines did not find the death rate by freezing to be logarithmic over its entire course. Death was logarithmic for about 75 per cent of the population after which a slower rate was evident for the remaining 25 per cent. He believed death to be due to denaturation of cellular proteins. Examination of suspensions of bacteria before and after freezing in different ways, did not reveal rupture of bacterial cells to any extent.

Just what happens in the bacterial cell when it is frozen, is a question that has not been answered. Results of experiments by Haines¹⁰⁹ are pertinent. Aqueous suspensions of cells from young cultures, usually 20 hours old, were prepared and small quantities were frozen rapidly with solid carbon dioxide at $-70^{\circ}\text{C}.$ ($-94^{\circ}\text{F}.$). Variable counts of viable microorganisms were secured with the several cultures used before and after freezing. With the most susceptible organism, *Pseudomonas pyocyaneus*, about 80 per cent of the cells were killed, with *Escherichia coli* about 40 per cent, and with the spores of *Bacillus mesentericus* about 27 per cent. The rate of freezing seemed to have little effect on the proportion of cells killed. Since freezing is presumably slower at $-5^{\circ}\text{C}.$ ($23^{\circ}\text{F}.$) than at $-70^{\circ}\text{C}.$ ($-94^{\circ}\text{F}.$) and since larger ice crystals ought to be formed at the former temperature than at the latter, freezing at a slow rate ought to

107. Hess. 1934. Atlantic Fisheries Exp. Sta., J. Biol. Bd. Canada 1, 95-108.

108. Haines. 1933. Ann. Rept. Food Invest. Bd. for 1932, p. 48; also Repts. for 1935 and 1936

109. Haines. 1938. Proc. Roy. Soc., Ser. B. 124, 451-463; Bull. Hyg. 13, 476.

cause more destruction than at a high rate. Because Haines did not find this to be the case (there was no difference) he believed that the theory was untenable. Careful measurements of cells of large organisms, such as *Saccharomyces cerevisiae*, failed to show any significant change in size on freezing or on thawing. No evidence was obtained that alternate freezing and thawing had any disruptive effect on the cells. Very interesting results were obtained when bacterial suspensions, which had been frozen rapidly at $-70^{\circ}\text{C}.$ ($-94^{\circ}\text{F}.$), were stored at different temperatures below zero and examined from time to time. At $-20^{\circ}\text{C}.$ ($-4^{\circ}\text{F}.$) the rate of death was slow; for instance, with *Escherichia coli* 25 per cent of the organisms were still alive after storage for 163 days. At $-1^{\circ}\text{C}.$ ($30.2^{\circ}\text{F}.$) and $-2^{\circ}\text{C}.$ ($28.4^{\circ}\text{F}.$), on the other hand, death occurred rapidly, the viable population of *Escherichia coli* at $-2^{\circ}\text{C}.$ ($28.4^{\circ}\text{F}.$) being reduced to four per cent in 11 days. The effect was even more striking with *Pseudomonas pyocyaneus*, while with the spores of *Bacillus mesentericus* there was practically no difference between the rate of death at $-20^{\circ}\text{C}.$ ($-4^{\circ}\text{F}.$) and $-2^{\circ}\text{C}.$ ($28.4^{\circ}\text{F}.$). These findings suggest that there is a critical temperature of storage in the frozen state for bacteria analogous to that of muscle and approximating $-1^{\circ}\text{C}.$ ($30.2^{\circ}\text{F}.$) to $-2^{\circ}\text{C}.$ ($28.4^{\circ}\text{F}.$).

In view of these results and others not discussed here, Haines considered it probable that death of bacteria in the frozen state is due to some change in one moiety of the cellular proteins leading to denaturation and subsequent flocculation. The success of methods of rapid freezing, with desiccation, for the storage of bacteria and sera is probably due to the fact that under such conditions no denaturation of the proteins occurs. It is interesting to note that, though no protein flocculation was demonstrable as the result of a single freezing and thawing, nevertheless some vegetative organisms experienced a high mortality during this process. A similar phenomenon has been observed in the death of muscle, and is interpreted as being due to a time lag. Presumably some change is brought about in the organization of the cellular proteins which is sufficient to destroy the vitality of the cell without producing actual coagulation. Experiments of a similar nature were also made by McFarlane,¹¹⁰ results of which showed the complexity of the question. Presence of hydrogen ions hastened destruction of yeast cells by freezing. The significance of McFarlane's results justifies more extended review.

Cells of a cold-tolerant *Saccharomyces* species and of *Escherichia coli* were suspended in distilled water and in 1, 5, 10, 15, 20, 30, and 50 per cent sucrose solutions. In three series of experiments these media were adjusted to pH 6.5, 5, and 3.6 to 3.7. The suspensions were dispensed in 10-ml. quantities in sterile pyrex test tubes. The tubes were stoppered with sterile corks; half were stored at $-10^{\circ}\text{C}.$ ($14^{\circ}\text{F}.$) in still air and half at $-20^{\circ}\text{C}.$ ($-4^{\circ}\text{F}.$). The number of viable microbial cells surviving different storage intervals in each frozen suspension was determined by plate count.

110. McFarlane. 1940. Food Research 5, 43-57; 6. (1941), 481-492; 7 (1942) 509.

After several weeks' storage at -10°C. (14°F.) or at -20°C. (-4°F.) the number of viable microorganisms in the different sucrose media of a given pH series did not always vary as the concentrations of sucrose except when the hydrogen-ion concentration of the series was high (pH 3.6 to 3.7). When the series of sucrose media possessed a reaction, pH 6.5 or 5, there were fewer viable yeast cells after several weeks' storage in some of the intermediate concentrations of sucrose. The same observation was made with regard to the survival of *Escherichia coli* in sucrose media of pH 5. Higher concentrations of sucrose, 30 to 50 per cent, tended to retard destruction of the two microorganisms. There was less destruction of yeast cells in distilled water after long storage periods than in some of the lower concentrations of sucrose, especially at -20°C. (-4°F.). On the other hand, greater destruction of *Escherichia coli* tended to take place in distilled water than in any of the sucrose concentrations tested.

When the hydrogen-ion concentration was the only variable, a reaction of pH 6.5 was found to be more favorable than a reaction of pH 5 for hastening the destruction of yeast cells in some of the sucrose media; but in the case of *Escherichia coli* the experimental evidence indicated greater destruction occurred in those samples which possessed the greater hydrogen-ion concentration. Of the conditions investigated the most destructive for both microorganisms was pH 3.6 to 3.7.

When temperature was the only variable, greater kills, after several weeks' storage, tended to occur at -10°C. (14°F.) than at -20°C. (-4°F.).

From these results and those of Berry¹¹¹ and Haines, it is evident that microorganisms are apparently destroyed more quickly at lower temperatures. Haines froze suspensions rapidly at -70°C. (-94°F.) and stored them at temperatures between -20°C. (-4°F.) and -1°C. (30.2°F.). Death was most rapid between -1°C. (30.2°F.) and -5°C. (23°F.). Berry¹¹¹ found that death more rapid in frozen fruits at -9.4°C. (15°F.) than at -20.6°C. (-5°F.). Presence of carbon dioxide had no influence.

The constitution of the menstruum in which organisms are frozen seems to have some influence. McFarlane¹¹⁰ observed that higher concentrations of sucrose than 30 and 35 per cent tended to retard destruction of a cold-resistant *Saccharomyces* and *Escherichia coli*. Freezing also had a more destructive effect on these species at pH 3.6 to 3.7.

Growth of Microorganisms Below Freezing. It has been generally believed that microorganisms cannot grow below freezing. The explanation has usually been that absence of sufficient water would prevent metabolism and growth. Apparently this is untenable, for considerable evidence exists to show that some microorganisms are able to develop. Proof of this is found in the literature. Frozen foods prompted further investigations. Berry and Magoon¹¹² demonstrated it with various species isolated from frozen fruits and vegetables. They found growth to be slow although a strain of *Pseudomonas fluorescens* in three per cent sodium chloride broth

111. Berry. 1936. Proc. Amer. Soc. Hort. Sci. 33, 224-226.

112. Berry and Magoon. 1934. Phytopathology 24, 780-796.

increased at $-4^{\circ}\text{C}.$ ($24.8^{\circ}\text{F}.$) from 200,000 to 6,000,000 per ml. in 36 days. Smart¹¹³ observed growth with eight species held at $-8.89^{\circ}\text{C}.$ ($16^{\circ}\text{F}.$). A few others grew after they had been held at room temperature. Haines¹¹⁴ also made similar observations. The Frozen Pack Laboratory of the United States Department of Agriculture, as reported by Berry,¹¹⁵ observed the deadline for microbial growth to be somewhere between $-9.4^{\circ}\text{C}.$ ($15^{\circ}\text{F}.$) and $-6.67^{\circ}\text{C}.$ ($20^{\circ}\text{F}.$). Certain members of the genera *Cladosporium* and *Sporotrichum* were not inhibited at $-6.67^{\circ}\text{C}.$ ($20^{\circ}\text{F}.$). False yeasts were found to grow at this temperature. Several frozen fruits and vegetables stored for three and one-half years in non-airtight containers showed no bacterial growth. Under aerobic conditions, *Cladosporium* sp. and *Torula* sp. grew at $-18.9^{\circ}\text{C}.$ ($-2^{\circ}\text{F}.$) and *Pseudomonas* at $-20^{\circ}\text{C}.$ ($-4^{\circ}\text{F}.$). Many factors in the environment of the cells influence the death rate.

Effect of Freezing on Pathogenic Microorganisms in Foods. Preservation of foods by freezing introduced new problems. Since some of the raw materials may harbor pathogenic bacteria or other species which elaborate products that are toxic by mouth, it is desirable to ascertain the effects of freezing on such microorganisms. Because freezing does not destroy all microorganisms the behavior of those which survive is of considerable consequence. In order to determine whether common pathogens could survive in frozen fruits, Wallace and Tanner¹¹⁶ inoculated cherries and cherry juice with cultures of *Eberthella typhosa*, *Salmonella schottmülleri*, *Salmonella aertrycke*, *Escherichia coli*, and *Proteus vulgaris*. The inoculated fruits were sealed in suitable containers and stored at $-17.8^{\circ}\text{C}.$ ($0^{\circ}\text{F}.$) and $-40^{\circ}\text{C}.$ ($-40^{\circ}\text{F}.$) for 20 weeks in the case of the cherries and four weeks in the case of the cherry juice. In the latter the organisms survived for less than four weeks and in the cherries for two to three months. Such results indicate that efforts should be made to safeguard the picking and handling of such products for they receive no treatment which will destroy objectionable microorganisms. Experiments of a similar nature were made with sliced, sweetened strawberries by McCleskey and Christopher.¹¹⁷ After storage at $-18^{\circ}\text{C}.$ ($-4^{\circ}\text{F}.$) the following survival periods were reported: *Eberthella typhosa*, six months; *Staphylococcus aureus*, five months; *Salmonella aertrycke*, and *Salmonella schottmülleri*, one month; *Salmonella paratyphi*, not recovered at any time from the frozen berries. *Eberthella typhosa* inoculated into unsliced, sweetened berries was present in small numbers after 14 months' storage at $-18^{\circ}\text{C}.$ ($-4^{\circ}\text{F}.$). At room temperatures, the death rate of *Eberthella typhosa* was very rapid; heavily inoculated berries were free of living organisms in six hours. At $5^{\circ}\text{C}.$ ($41^{\circ}\text{F}.$) 98 per cent of the cells were killed in one day and sterility was reached in eight days.

Effect of Freezing on Toxicogenic Microorganisms in Foods. Microorganisms which elaborate products that are toxic by mouths have caused

much trouble in the food-preservation industry. Canned vegetables and meats have been especially involved. They are foods in which the general flora has been greatly simplified by heat so that the field has been left for those which survived. In frozen foods this is not the case. Those organisms which form toxins must compete with all of the others present. Some may favor their growth while others may inhibit it. Up to the present time frozen foods have been quite free from health hazards. Only one outbreak has been traced to frozen fish. That *Clostridium botulinum* is present on vegetables to be frozen is admitted. Wallace and Tanner¹¹⁶ observed that frozen foods inoculated with *Clostridium botulinum* were not hazardous as long as they were kept frozen. They stated that data from these studies would indicate that if foods were prepared properly and used immediately after defrosting there is little danger of botulism from frozen foods. Toxin is not readily destroyed by freezing, but there is little chance of toxin being present in properly prepared frozen foods. Toxin was not produced before freezing or, with few exceptions, during freezing. It must be remembered that the inoculations used were massive compared with the natural inoculation encountered in food. The spores of *Clostridium botulinum* are resistant to freezing, and once in frozen food they probably remain there for long periods of time. This is not of great importance if foods are frozen properly and if they are consumed soon after thawing. If foods containing spores are allowed to thaw and stand at room temperature for several days before using, they may become dangerous. The possibility of botulism from mishandled frozen vegetables was looked into by Straka and James.¹¹⁸ Samples prepared and inoculated in the Northwest were packed in sealed tin cans, in glass, and in paper cartons. These containers were used to give varying conditions of anaerobiosis. Some of the containers were closed under vacuum. Heavy and light inoculations with toxin-free spores of a mixture of *Clostridium botulinum*, types A and B, were used. Two of 24 tin containers of uninoculated peas, most of which were held for three days after defrosting, were toxic; eight others were shown to harbor *Clostridium botulinum*. The contents of some of the packages which had received both light and heavy inoculation were toxic several days after defrosting, showing that freezing did not kill the spores and that frozen foods which are not properly handled may become poisonous. In general, peas which became toxic were badly spoiled.

Dried spores of *Clostridium botulinum*, according to James,¹¹⁹ are not killed or materially reduced in numbers by either slow- or quick-freezing. Botulinum toxin frozen and defrosted 15 times was not reduced in strength. In another paper more data on the same subject were reported by Straka and James.¹²⁰ Seventy-two glass containers, 24 uninoculated, 24 with light inoculation, and 24 with heavy inoculation, were examined. No toxin was present in peas which had just been defrosted or which had been

118. Straka and James. 1932. Amer. J. Pub. Health 22, 473-492.

held in the icebox for three days. It is interesting that one of 24 uninoculated jars was toxic while positive cultures for *Clostridium botulinum* were secured from eight other containers. A few toxic jars were found in the inoculated jars, more occurring in those which had received heavy inoculation.

All the experiments were with frozen peas and all were concerned with the toxins of *Clostridium botulinum*. Sixty experimental containers of frozen peas were examined for this organism. Of these 30 were uninoculated controls and *Clostridium botulinum* was isolated from 15 of them. The other 30 were inoculated with this organism (one million spores per container) which was recovered in each case. Of 83 uninoculated controls defrosted and held at various temperatures 26.6, 15.5, and 10°C. (80, 60, and 50°F.) for two to seven days, one gave positive evidence of a weak toxin. Of 15 containers receiving a dilute inoculum of these spores, defrosted and held at 80°F. for two days, none gave any evidence of toxin. Of 100 containers receiving a concentrated inoculum 30 were defrosted and held at 26.6°C. (80°F.) for two days; 15 were defrosted and held at 15.5°C. (60°F.) for six days; 15 were defrosted and held at 15.5°C. (60°F.) for three days; 30 were defrosted and held at 10°C. (50°F.) for seven days; and 10 were defrosted and held at 5.5°C. (42°F.) for seven days. Of these samples nine gave definite evidence of toxin; six had been held at 26.6°C. (80°F.) for two days and three at 10°C. (50°F.) for seven days. The authors conclude that when peas preserved by freezing are properly handled there is no danger of botulism.

Some frozen-food specialists do not view the botulism situation with respect to frozen foods with much alarm. They base their assurance on the fact that there is little danger from properly handled frozen foods. Diehl¹²¹ has stated that apprehension as to the public-health aspect of canned foods, need not be entertained. Such statements fail to recognize that many food-poisoning outbreaks are caused by foods which are not properly handled. If foodstuffs were properly handled there would probably be no food-poisoning outbreaks. Berry¹²² placed much reliance on the fact that lactic acid bacteria exist in frozen foods and that they might form enough acid to inhibit toxicogenic organisms which could not tolerate such acid. He states: "Considering the unfavorable influence of organisms of these types on *Clostridium botulinum* and the fact that, in actual test, upwards of 100 containers of frozen-pack vegetables, chiefly peas, artificially inoculated one to one and one-half years previously with from four to 10 million spores of *Clostridium botulinum*, types A and B, uniformly underwent souring on standing and failed to become toxic, the possibility of botulism from frozen products seems remote. While with appropriate technic *Clostridium botulinum* has been recovered in pure culture from vegetables inoculated 19 months previously and stored at -9.4°C. (15°F.) and the toxicity of the A type at least has been well maintained, it certainly appears that, as frozen-pack vegetables are han-

121. Diehl. 1938. *The Canner*, Feb. 19, 15-17.

122. Berry. 1933. *Canning Age*, Oct., 1933, 446-447.

dled in practice, botulism organisms if present at all, do not have a chance to develop. Thus the uncertainty and even anxiety which formerly surrounded the freezing preservation of vegetables, though commendable at the time, appeared in the light of the more complete knowledge to have been unnecessary."

This is a strong position for anyone to take. It is doubtful whether lactic acid bacteria would always be present in all frozen vegetables unless they were placed there by inoculation. Furthermore, Meyer and Gunnison,¹²³ in a Bartlett pear outbreak of botulism, attributed the ability of *Clostridium botulinum* to develop in a food which was so acid (pH 3.86) to the presence of yeasts and members of lactobacilli group which used the acid. The experience with forage poisoning in cattle, which may be botulism, again showed that *Clostridium botulinum* could develop in an acid environment. In this case, molds were believed to make alkaline areas or pockets in the silage in which *Clostridium botulinum* could grow. Such situations could easily occur in frozen foods.

Enterotoxin-producing bacteria, such as Staphylococci, would also be of interest in frozen foods. Jones and Lochhead¹²⁴ found that they survived freezing in vegetables. Fifty different types of Staphylococci were isolated. Using corn, Jones and Lochhead showed that enterotoxin-producing Staphylococci could rapidly develop at room temperature, 20°C. (68°F.), but at 4.4°C. (40°F.) no multiplication was observed. Using 18 strains which produced enterotoxin, eight strains still produced toxin in frozen corn defrosted at room temperature but none in corn defrosted at from 4.4 to 10°C. (40 to 50°F.).

Such work as just reviewed does not indicate that frozen foods need be dangerous but that they must be carefully handled and kept frozen. Installation of many freezing lockers in America makes it imperative that sound practices be followed by those who operate them.

HIGH TEMPERATURES

The marked susceptibility of bacteria to high temperatures has made possible the best known and most reliable methods of food preservation. Mere heating of bacteria in various menstrua does not always destroy them; for instance, Rahn,⁴⁹ Fay,¹²⁵ and Baumgartner and Wallace¹²⁶ have shown that heavy sirups and foods containing large amounts of sugar are not as easily rid of microorganisms by heat as are lighter sirups. Rahn⁴⁹ first reported the observation after heating yeasts in sugar solutions. Baumgartner and Wallace carried out experiments using spores of an anaerobic and an aerobic organism; in concentrations up to 50 per cent sucrose no effect on the thermal resistance of spores in acid or alkaline solution was observed. This was believed to be due to the resistant spore envelope. In the case of the vegetative cell, tests using *Escherichia coli* show that a minimum concentration of about 10 per cent sucrose affords

appreciable protection at pasteurizing temperatures in neutral solutions. This protective action varied directly with the sugar concentration. In very acid solutions, such as fruit sirup, however, this effect is masked by the toxicity of the hydrogen ion.

Strains of *Torula*, heated in varying sugar concentrations in neutral solution, showed no increase in thermal resistance. As would be expected, a sugar-tolerant strain also proved insensitive in this respect. A concentration of up to 50 to 55 per cent sucrose has no inhibitive action on either the vegetative growth or spore germination of the organisms encountered in underprocessed fruit. The inhibiting factor in such cases appeared to be one of acidity. An increase of pH up to the maximum for growth of the organisms concerned had no lowering effect on the sugar tolerance.

Fay¹²⁵ observed a protective action of sugars on *Escherichia coli*. The protective action increased with the osmotic pressure but equimolar solutions of different sugars did not show the same protective action. Fay pointed out that this may occur in heat sterilization of various foods containing sugar. Beamer and Tanner¹²⁷ also noticed the effect of increasing sugar concentrations on thermal resistance of microorganisms.

Pasteurization. This is a process in which the food materials are heated below the boiling point for various lengths of time. Pasteur preserved beer and vinegar by pasteurization. Today, fruit juices are preserved by pasteurization because this treatment causes little change in flavor and aroma. Since the temperatures used are considerably below the boiling point, foods preserved in part by pasteurization may have to be held in a cool place to absolutely keep them.

Boiling. Boiling probably has greater effect on bacteria in food than pasteurization. It may not be a reliable heat treatment, however. Whether or not it is a safe step depends on several factors, such as altitude, size of the food mass, and reaction. Bitter's¹²⁸ work on heat penetration into large sausages indicated that even after prolonged boiling the rise in temperature at the center of the mass was very slow. In the first procedures for the so-called cold-pack process for canning foods, the United States Department of Agriculture advised processing in boiling water. The outbreaks of botulism traced to foods processed in this manner caused the Department of Agriculture to finally recommend the pressure cooker for nonacid foods.

Processing (Canning): Preservation of foods by canning and packing in glass jars has become a great industry. The subject will be discussed in a later chapter. The method involves preservation of the food in hermetically sealed tin or glass containers. The canner attempts to destroy bacteria in food by high temperatures and to hold it under conditions which prevent the ingress of other bacteria.

FERMENTATION

Certain foods are also preserved by the products of fermentation. Milk, vegetables, and meats may be preserved in this manner. Carbo-

128. Bitter. 1911. Hyg. Rundschau, 181-189.

hydrates in the foods, or extracted from them, are fermented to organic acids, among which lactic acid predominates. These acids make it impossible for putrefactive bacteria to function. Fermented foods have a characteristic flavor.

DEHYDRATION

Foods have been preserved for centuries by drying. It was probably one of the first methods to be used by primitive man for preserving meat and vegetables. He soon learned the value of smoke as an adjunct to drying. Cruess¹²⁹ stated that the Boer War and the first World War greatly stimulated interest in drying as a means of food preservation. Prescott stated that dried vegetables were used during the Civil War to prevent scurvy. Cruess and Mrak¹³⁰ questioned their ability to function in this manner in view of the methods used for drying at that time.

Microorganisms cannot endure absence of water indefinitely. While they seem to get along without it for long periods, they eventually die. Man has used drying for preservation of cereals, meats, fruits, and vegetables. Much attention was given to dehydration of foods during the first World War, and while many different dehydrated foods were placed on the market, they have gradually disappeared. The main reasons for this are probably the marked alteration in flavors, and the fact that methods of preservation are available with which the consumer is more familiar. Nichols,¹³¹ after a comprehensive review of literature and public-health aspects of dried fruits, vegetables, eggs, milk, fish, and meats, concluded that these foods presented no great health hazard. Only four outbreaks of illness have been attributed to dried foods; most of the evidence suggests contamination after preparation. Dehydration of fruit was considered preferable to sun drying.

Considerable discussion is given to the possible disadvantages of the use of sulfur dioxide or sulfites in the drying of certain fruits. Sulfur dioxide is largely used to preserve the natural color. The evidence presented by Nichols is in favor of its harmlessness. The average amounts absorbed are given as between 2,000 and 3,000 parts per million for apricots, peaches, and pears for good color retention; with apples less is required. Results of investigations suggest that the sulfur dioxide has a destructive effect upon thiamin but not on vitamin A or ascorbic acid, retention of which is indeed improved. Restrictive limitations against sulfur dioxide retention are not required or should be liberal.

According to Clague¹³² numbers of microorganisms on dried foods vary from a few thousand per gram as a maximum on dried fruits up to several millions per gram on dried vegetables. Tests conducted with a small tunnel drier showed that artificial drying, or dehydration, effectively eliminated yeasts and materially reduced the numbers of bacteria and molds on dried fruits. *Escherichia coli* inoculated on the surface of grapes

132. Clague. 1936. Food Research 1, 45-59.

was destroyed by the drying process. Reduction of the number of microorganisms on vegetables during the drying process was not so marked as on the fruits. In fact, dehydration did not completely kill *Escherichia coli* although the blanching process which ordinarily precedes dehydration was effective in eliminating this organism. Types of microorganisms found on dried foods were for the most part Gram-positive, sporulating bacteria and molds, although Gram-negative bacteria and yeasts were occasionally observed. Lactose fermenters, not of the *Escherichia coli* type, were found in dried vegetables.

Modern methods of dehydration have been reviewed by Nichols, Powers, Gross, and Noel.¹³³ Whether the second World War will accomplish for dehydrated foods what the first did not remains to be seen. With the exception of certain meat products, fruits, eggs, and milk, dried foods have never been widely accepted in the United States. As this is written in the summer of 1942 much more consideration is being given them in order to conserve as much space as possible in shipment of foods to other countries.

CARBON DIOXIDE

Atmospheres of carbon dioxide have been used for many years for preserving foods from attack by microorganisms. Owing to the fact that microorganisms respond in different manners to this gas, some being inhibited and development of others enhanced, the results have been variable. Carbon dioxide today is used mainly along with low temperatures and with freezing. Killeffer¹³⁴ reviewed in a general way the results along these lines up to 1930. Much has been done, however, since then with more success. Franks¹³⁵ was issued a patent for keeping fruits and vegetables fresh under a carbon dioxide pressure of 60 pounds per square inch applied in such a manner that "air and obnoxious germs" were eliminated. Air was removed by discharging the gas several times and recharging. The use of this gas for fruit preservation since this time has involved much lower concentrations of carbon dioxide. "Gas storage" of apples in an atmosphere of 12 to 15 per cent of carbon dioxide has been found to be advantageous by Kidd, West,¹³⁶ and others in England.

Moran¹³⁷ pointed out that storage in carbon dioxide is not a new method of preservation. It is a more elaborate method of cold storage involving in addition to control of temperature and humidity, control of the composition of the gaseous atmosphere. Addition of this factor makes it possible to do for some foods what temperature and humidity alone cannot do. Carbon dioxide was found to show variable effects on molds according to the medium. Growth of *Rhizopus nigricans* on two per cent malt agar and on acidified malt agar was reduced as concentration of carbon dioxide increased. On an alkaline medium more carbon dioxide was necessary to restrict growth than on an acid medium. Concentrations

up to 20 per cent under some conditions were found to favor growth. Two and one-half per cent concentration of carbon dioxide in meat storage boxes was found to prolong the keeping quality of meat by Mallmann and Zaikowski.¹³⁸ These observations were made on 74 cultures of bacteria representing various genera isolated from beef.

According to Moran,¹³⁹ Moran and Smith,¹⁴⁰ Smith¹⁴¹ and Tomkins¹⁴² germination of *Thamnidium*, *Mucor*, and *Cladosporium* was delayed and growth markedly inhibited in air containing as little as four per cent of carbon dioxide. In 20 per cent carbon dioxide the rate of growth was one-half to one-fifth that in air, the inhibition being more marked the lower the temperature. Their experiments showed that development of the naturally accumulated microflora in stale meat was retarded by action of carbon dioxide to less than 10 per cent of the normal rate. Out of 37 different species of bacteria studied only five proved to be stable to the action of carbon dioxide. At lower temperatures the depressing qualities of carbon dioxide were manifested to a lesser degree. Later work by Tomkins¹⁴³ indicated that presence of carbon dioxide might even favor development of molds on foods. Carbon dioxide dissolves in them to alter their pH in a direction which favors growth of microorganisms. Concentrations up to 20 per cent may encourage mold growth.

That general statements cannot be made about effects of carbon dioxide on microorganisms is indicated by Hes,¹⁴⁴ who established three groups according to their reactions to it: (1) autotrophic organisms, such as nitrifying and sulfur bacteria, which utilize carbon dioxide as a source of carbon; (2) parasitic bacteria which grow better in an atmosphere enriched with carbon dioxide than in air; and (3) bacteria which require only traces of carbon dioxide. Stewart¹⁴⁵ observed extreme sensitivity of *Achromobacter* to carbon dioxide with little effect on *Aerobacter cloacae*. Harmful effects of carbon dioxide were not attributed to acidity. Haines¹⁴⁶ applied carbon dioxide at 20°C. (68°F.) in 60 to 80 per cent concentrations to nine strains of *Pseudomonas* species and noticed considerable variation. Two strains were scarcely affected. *Bacterium pyocyaneus* and *Escherichia coli* were not affected at all. At lower temperatures, however, between 15°C. (59°F.) and 10°C. (50°F.), the effect of 60 per cent carbon dioxide was decided. While growth occurred at the higher temperature in eight days, none occurred in six months at 10°C. (50°F.). The organisms were not destroyed as shown by other experiments.

In Coyne's¹⁴⁷ experiments growth of a number of bacteria in the presence of different amounts of carbon dioxide from 5 to 100 per cent at 0, 10,

25, and 37°C.(32, 50, 77, and 98.6°F.) showed that, in general, carbon dioxide exercised an inhibitory action on growth varying from complete inhibition in some cases to an almost negligible effect in others. At temperatures below optimum for growth the influence was invariably more marked. In 20 per cent of carbon dioxide at 0°C., growth of bacteria responsible for spoilage of fresh fish is almost completely inhibited. Haines made counts of viable bacterial species to determine their rate of growth in nutrient broth saturated with air and air containing 10 per cent and 20 per cent of carbon dioxide, respectively, at 20, 4, and 0°C. (68, 39.2, and 32°F.). In these concentrations carbon dioxide had but little effect on *Proteus*; it increased the lag period and lengthened the generation time by about one-half for *Pseudomonas* and *Achromobacter* at 20°C. On the last two organisms the effect was more marked at a lower temperature, the generation time being more than doubled by 10 per cent of carbon dioxide at 0°C. Change in pH did not explain the retarding effect of carbon dioxide. Results of similar investigations with actual foods, such as ice cream and milk, by Salmon and LeGall¹⁴⁸ showed that in highly buffered menstrua the bactericidal effects of carbon dioxide were negligible. Pure-culture studies with various microorganisms showed that the inhibition obtained in poorly buffered media were analogous to those with the same organisms on an agar medium adjusted to a corresponding pH.

When 30 to 100 per cent carbon dioxide was supplied, considerable increase in acidity was observed. By buffering the agar medium deleterious effects were greatly lessened or entirely prevented, depending on degree of buffering. More than 100 species representing various bacterial groups were studied as to carbon dioxide requirements. Growth inhibition was obtained by removal of carbon dioxide from the cultural environment. Many organisms were actually killed in 24 hours under carbon dioxide-free conditions. The carbon dioxide requirements of various strains and species varied within wide limits. Growth of many organisms was greatly facilitated by small increments of added carbon dioxide (above ordinary atmospheric carbon dioxide). *Lactobacillus acidophilus*, *Bacterium pullorum*, and *Bacterium pneumoniae* are good examples (Valley and Rettger¹⁴⁹).

Carbon dioxide has been used to control development of mold on bread. Skovholt and Bailey¹⁵⁰ found that while 17-per cent concentrations would suppress mold spores, they were not killed and would develop unless this concentration was maintained.

Carbon dioxide has also been used for preserving strawberries during shipment; 25 per cent in the atmosphere held berries in good condition over a 14-hour period at 10 to 12.78°C.(50 to 55°F.), according to van Doren.¹⁵¹ According to Tomkins¹⁵² 20 per cent of carbon dioxide might enhance rather than restrict development of certain molds. Haines be-

lieved that carbon dioxide was not a bactericide but a marked inhibitor of growth. Successful application of it to storage of meat depends on the chance that the flora present is susceptible to it.

Sides of bacon were kept successfully by Callow¹⁵³ for eight months at $-10^{\circ}\text{C}.$ ($14^{\circ}\text{F}.$) in carbon dioxide provided they were first frozen at $-20^{\circ}\text{C}.$ ($-4^{\circ}\text{F}.$). He found that carbon dioxide delayed development of rancidity for seven months. Air-stored bacon was rancid after four months, and after 12 months it was too rancid to be edible, while the gas-stored bacon was just beginning to show signs of rancidity.

Another situation which cannot be overlooked in gas storage of foods is due to deteriorative changes which may result from carbon dioxide. Brooks¹⁵⁴ found no discoloration of beef in 10 per cent carbon dioxide. In 35 per cent, the color was only fair to poor.

OZONE

Ozone is a powerful germicide when it can reach naked microorganisms. When the latter are imbedded in organic matter, ozone may not exert appreciable effect. It has been recommended as a deodorizer and it was hoped that it would also function as a bactericide. While many statements have been made about this property, few are based on results of experiments and are somewhat contradictory. Haines¹⁵⁶ observed variation in resistance of bacteria to ozone. Staphylococci and *Proteus* were sensitive to ozone while *Achromobacter* was less so. Much more was needed to control large numbers than few, and actively growing cultures decomposed it. The germicidal concentration of ozone toward *Achromobacter*, introduced when the inoculum was made, appeared to be 300 p.p.m. by volume at $20^{\circ}\text{C}.$ ($68^{\circ}\text{F}.$) and 10 to 100 p.p.m. by volume at $0^{\circ}\text{C}.$ ($32^{\circ}\text{F}.$). In the next report, Haines¹⁵⁷ published results of experiments with other microorganisms under other conditions. Variations in results were observed when the bacteria were grown on agar or in broth. *Pseudomonas* and *Achromobacter* spores were more resistant than Staphylococci, *Proteus*, *Bacillus subtilis*, or *Bacillus mesentericus*. In general, the order of susceptibility toward ozone was just opposite to that toward carbon dioxide. When the bacteria were allowed to multiply much more ozone was necessary to destroy them. Bacteria suspended in water were readily destroyed by ozone. Suspensions containing one million organisms per milliliter were sterilized in two hours by 100 p.p.m. by volume. The curve was not logarithmic over its entire range.

When molds were growing on malt agar, concentrations of ozone required to inhibit them were the same as those required for bacteria. Haines believed that concentrations between 10 and 1,000 p.p.m. by volume would be necessary for inhibition of microorganisms depending on temperature, humidity, medium, and age of the culture.

157. Haines. 1935. Idem for 1934, 44-47.

Haines also applied ozone to meat and eggs in storage. With meat, no difference in the time of onset of "slime" could be detected between meat stored in ozonized and in ordinary air. Eggs stored in ozonized air containing 10 p.p.m. by volume for five months had "off-flavors"; three p.p.m. of ozone in the air, however, did not produce this flavor and inhibited molds markedly. Haines¹⁵⁸ believed that much of the ozone in the presence of organic matter is dissipated by reacting with it because smaller amounts were required where the bacteria were in saline media. Haines¹⁵⁹ claimed that the value of ozone would be greatest when applied during the lag phase and in presence of the minimum of nutriment. A marked advantage of ozone in meat storage was diminution of the "bad-meat" smell. Haines was led to conclude that ozone was of little value in inhibiting growth of bacteria on stored tissues; the concentrations required to be effective are higher than those which can be tolerated by human beings, have a deleterious effect on the fat of the carcass, and even in the case of eggs cause "strong" flavors to be developed in the yolk. Haines stated that the practical value of the gas was greatest when it could be applied during the lag-phase of growth and in presence of minimum nutrients.

Ozone, as is the case with carbon dioxide, also causes deteriorative changes to occur in fatty constituents of foods. Lea¹⁶⁰ found beef fat, egg oil, and lard to oxidize rapidly in presence of ozone. In ozonized air the fats assumed the characteristic cucumber as well as tallowy odor in 12 days.

Ewell¹⁶¹ has reported that except in special cases ozone is the best available agent for improving and prolonging the storage of foodstuffs. The growth of mold on eggs stored in an atmosphere of high humidity can be prevented by maintaining an ozone concentration 1.5-2 p.p.m. in air of the aisles between the egg cases. This gives a concentration of about .6 p.p.m. of ozone within the egg cases. The growth of mold on meat can also be prevented by maintaining an ozone concentration of about 1.5 p.p.m. in the storage-room atmosphere. The safe storage period for many fruits and vegetables can be prolonged by the use of ozone. High concentrations of ozone (50 p.p.m.) may injure such products as bacon, lard, butter, cream, dried eggs, meat, and bananas. The effect of ozone on oxidizable material is roughly proportional to the amount of ozone in contact with the surface. Heiling and Scupin¹⁶² found ozone to be more lethal for fungus spores than for bacteria.

Molds are especially troublesome in storage of certain foods under refrigeration for relatively long periods. Haines found that they were susceptible to ozone while Lea¹⁶³ stated that high concentrations must

be used for long periods to destroy them. Spores of four species were found to be capable of germination after exposure to 400 p.p.m. of ozone for 10 to 15 hours but were killed within 20 hours. Smaller concentrations inhibited germination and growth. Spores sown on bacon, sausage, etc, failed to germinate at 9°C.(48.2°F.) in atmospheres containing as little as .5 p.p.m., and similar concentration prevented development of hyphae already present. Ewell¹⁶⁴ observed that destruction of microorganisms was related to both ozone concentration and time of application. A given concentration produced about the same lethal effect at 4°C.(39.2°F.) as at 20°C.(68°F.).

Opinions with respect to ozone or ionized oxygen as a practical agent for microorganism control are not always in agreement. One authority¹⁶⁵ stated that with a continuous concentration of one of two parts of ozone, at the end of eight months, eggs may be as fresh as when stored. With special attention to temperature and humidity, they may be kept for 15 months.

Ewell¹⁶⁶ has stated that .6 p.p.m. of ozone is necessary in the atmosphere to prevent development of bacterial and fungus growth in egg rooms. A concentration of 2 p.p.m. in meat rooms was said to be sufficient for this purpose.

FOOD PRESERVATION WITH ULTRAVIOLET LIGHT

Although the lethal effects of ultraviolet light have been known for many years when applied to unprotected cells under certain conditions in the laboratory, and its limitations appreciated, it is being heralded again for new uses in practically all industries where it is desirable to destroy certain microorganisms or where the general flora of microorganisms must be reduced to a minimum. That this form of energy is lethal to living matter, when it reaches it directly and when living matter such as bacterial cells are directly exposed to it, cannot be denied. Skeptics may raise the question, however, whether results secured in the laboratory under the most ideal conditions, where the rays may penetrate or be absorbed to the maximum, have any relation to those secured under practical conditions in the food-preservation industry. Does the fact that microorganisms are destroyed in the laboratory under most ideal conditions of exposure prove that they are destroyed also in foods where they may be protected by being imbedded and not even exposed to the rays? In other words, how much weight in the food-preservation industry should be given to pure-culture laboratory experiments in which microorganisms are exposed under conditions which do not obtain in practice? If one believes all of the enthusiastic statements in advertising literature prepared by those who make ultraviolet-producing lamps or the statements of salesmen who base their remarks mainly on a few dried-up, petri-dish cultures of bacteria, or even the observations of some in the meat industry who do not know the necessity of controlled experimental methods, the millenium has come

in food preservation. Owing to many factors, some of which have just been mentioned, this subject has become quite confused.

Several types of lamps under different trade names are now available for use in the food-preservation industry. The so-called "Sterilamp" has been widely advertised as an important adjunct in meat preservation and storage. Its use has been discussed by James¹⁶⁷ and Broadbent¹⁶⁸; both are from the laboratories of the concern which makes it. The "Sterilamp" is especially recommended for use in coolers in which meat is stored for aging and ripening. Such coolers are operated at higher temperatures and humidities which, of course, make microorganisms develop much faster. In order to keep them under some control, the meat is exposed to ultraviolet rays and the air is circulated at the same time. As applied to the meat industry Broadbent reported that four simple steps were involved:

1. Installation of Sterilamps in coolers, using a 30-inch lamp for every 30 to 40 square feet of floor area.
2. Raise the temperature to not exceeding 7.2°C.(45°F.).
3. Circulate the air in the cooler by means of a fan.
4. Raise the relative humidity to 90 per cent.

Over 80 per cent of the radiant energy from the "Sterilamp" is said to be in the region of 2537 Å. This is considered to be the most powerful permissible as a practical bactericide, by Ewell,¹⁶⁹ and superior to an atmosphere of ozone. If ozone were used to accomplish what ultraviolet light is claimed to do, its concentration would have to be so high that discoloration and rancidity would appear in meats. The germicidal properties of this lamp probably cannot be questioned under laboratory conditions where microorganisms are exposed directly to the rays. This has been definitely shown by Rentschler, Nagy, and Mouromseff.¹⁷⁰ They confirm what has been known for many years, i.e., that this form of energy is destructive to microorganisms when it can reach them.

Another type of lamp is known as the "Spertifier" and is also recommended by its manufacturers as most desirable in storage of foods, especially meats. This lamp is claimed to be specific in its action according to the wave length which it emits. The one recommended for meat coolers is claimed to reduce molds and bacteria causing slime on the surface of the carcass, to tenderize (ripen) the meat more quickly, to assist in retaining moisture and flavor, to destroy odors and to minimize trim losses. Some of these advantages are attained, not from exposure to ultraviolet rays, but to the fact that higher temperatures and humidities during storage are possible and that the air is circulated in the cooler by a fan. When the lamp known as the "Spertifier" is used, temperatures of 3.3°C. (38°F.) to 5.6°C.(42°F.) with relative humidities of 85 to 95 are recommended. These conditions are claimed to permit enzymes to act, render

tough meat more tender and to even raise its grade. Surface sterilization on the dark side of the meat could hardly be explained by action of ultraviolet light. Some agent formed by the light must be carried by air currents throughout the cooler or else movement of air in it by means of electric fans brings all bacteria-laden air in contact with the lamps.

The sum and substance of this method of holding meat is that by destroying surface bacteria on the meat in the cooler, it may be held at a higher temperature and humidity which allows the endotryptases to function more rapidly and completely. Once bacteria have been destroyed it is not necessary to keep the meat at low temperatures. This would suggest that some agent is emitted by the lamps which is carried in the air to the meat where it destroys surface microorganisms. With the older quartz lamps this may have been ozone. The fact that ozone is not germicidal to any extent in low concentrations would suggest that in the newer glass lamps emitting a wave-length of 2537 Å it is not the agent. Elwell stated that the latter lamps yield at the most only a few tenths of a part of ozone per million of air.

Ultraviolet light has recently come into considerable prominence in the United States through its recommendation for destruction and control of microorganisms in and on various foods (James,¹⁶⁷). Lea stated that those who wish to use it must determine for themselves whether microorganisms may be usefully reduced without introducing another form of spoilage. Much work has been done with bacterial cells under conditions which make it difficult to evaluate some of it. Various factors, such as type and species of microorganism, numbers of cells, distance, actual wave-length, and dosage, must be considered. Coblentz and Fulton¹⁷¹ found that less energy was necessary to kill *Escherichia coli* at wave-lengths shorter than 3050 Å than at longer wave lengths; as far as 3660 Å lethal action was apparent when heavy dosages were used.

While ultraviolet light is a powerful bactericide under some conditions when it can act directly on unprotected cells, its low penetrating power seriously interferes with its activity. Lea stated that effectiveness of ultraviolet light in destroying bacteria is comparatively low at wave lengths above 3100 Å but much greater between 2900 and 2250 Å. Radiation below 2250 Å is said to be even more efficient.

Studies of the effect of ultraviolet light on foods must consider the action of products of the quartz lamp other than rays. Chief among the latter is ozone. Most of the ozone is formed quite close to the lamp and is carried throughout the cooler in the moving air. Lea¹⁷² found that the presence of a few parts per million of ozone in the atmosphere greatly increased the rate of oxidation of fats and production of rancidity and consequent off-flavors. Lea believed that use of glass which would absorb ultra-short wave lengths while still transmitting fairly freely at 2536 Å would restrict formation of ozone. Moran¹⁷³ also observed that ozone

171. Coblentz and Fulton. 1924. Sci. Papers U. S. Bureau of Standards 19, 641.

172. Lea. 1936. Ann. Rept. Food Invest. Bd., 1935, 25; also Rept. for 1936, 37.

173. Moran 1937. Ann. Rept. Food Invest. Bd., 1936, 29.

produced by some lamps is a real disadvantage. Light rays do not penetrate. Surface organisms, as observed by Haines and Lea,¹⁷⁴ are readily destroyed but not just below the surface. A film of beef juice .2 mm. thick reduced the intensity of ultraviolet light a thousandfold. To be of reasonable value, foods must be exposed before much penetration of microorganisms has occurred. Possibility of undesirable changes from irradiation were also stressed by Dumeste.¹⁷⁵ He said that irregularities on the surface of the meat would prevent full success from use of the method. Only surface effects would be obtained since the ultraviolet light cannot penetrate to any extent. While bacteria are destroyed fat may be made rancid from its reaction with the ozone formed by the quartz tube. The lean meat may also be blackened.

Haines,¹⁷⁶ of the Low Temperature Research Station, University of Cambridge, stated that while ultraviolet light can, under certain conditions, kill or inhibit growth of bacteria and molds on foodstuffs, it also accelerates other and undesirable changes, e.g., oxidation of fats and formation of methemoglobin. Its use, therefore, in prolonging the storage life of foodstuffs is not straightforward. Experiments were carried out to determine how far the separate effects of the light can be controlled. In his early experiments Haines used a cold-type mercury-in-quartz lamp in which approximately 90 per cent of the light was that of wave-length 2536 Å. Appreciable amounts of ozone were formed. The older type quartz lamps have now been replaced by those made of glass which have greatly reduced ozone formation.

Beef fat exposed to ultraviolet light at a distance of 25 cm. for various periods of time by Lea caused appearance of a foreign odor in uncooked samples after five minutes' irradiation. Samples exposed for 10 minutes and cooked were unpalatable. Chemical changes induced in the fat were limited to a thin superficial layer. These data were from small pieces cooked in glass after irradiation. Lea thought it probable that greater deterioration could be tolerated in meat exposed and cooked in the normal manner. The tallowy odor, however, might be objectionable.

Quality is a property of meat which depends on more than one factor. Only one of them is tenderness, and this may not be the most important to some individuals. To some discriminating individuals flavor is just as important if not more so. Various investigations, results of which are discussed in these pages, indicate that irradiation of fresh beef with ultraviolet light affects flavor unfavorably. Most of the benefits which have been claimed for this process are based on greater tenderness resulting mainly from higher temperatures in the coolers during ripening. On these grounds, it has been stated that quality of meat has been raised one grade. Such a statement is only partly true, for many factors must be considered in grading beef. The question to be settled is whether good meat properly handled in clean coolers by competent, responsible men needs this special

174. Haines and Lea. 1937. *Idem* p. 30.

175. Dumeste. 1939. *Rev. generale du Froide* 20, 56.

treatment. Apparently many believe that it does not and among them are the largest meat-packing concerns in the United States. After reviewing the evidence Jones¹⁷⁷ believed the results of experimental work indicate that so far as meat is concerned, the advantages of irradiation with ultraviolet light are outweighed by the disadvantages, notably, loss of appearance and production of unpleasant flavors.

Moldy bread during hot, humid seasons is a real problem. This difficulty has been increased since loaves of bread have been sliced and wrapped. One method of coping with this difficulty is to irradiate the bread before and during slicing and thus attempt to eliminate distribution of the spores over freshly cut surfaces. Owen's¹⁷⁸ investigations indicated that some success might be attained. Irradiation sterilizes slicer saws as well as inactivates the spores. These results seem to agree with those of Welch and Perkins.¹⁷⁹ Although resistant molds exist, Welch found that 90 per cent were killed in one minute. Broadbent¹⁸⁰ also observed that molds required longer exposure than bacteria. Under ordinary conditions more lamps must be installed where a more difficult job is to be done. Tanner and Appling¹⁸¹ also observed differences in resistance to ultraviolet light among molds. Further work on the use of ultraviolet light in bakeries is discussed in a later chapter.

The Council of Physical Therapy of the American Medical Association¹⁸² recently discussed acceptance of ultraviolet lamps for disinfecting purposes. While their report concerned other situations than those which exist in the food industry, it is indirectly pertinent to it. It was stated that the spectral band at 2652 Å appeared to produce the maximum bactericidal action and that the emission band at 2537 Å is only 70 per cent as effective. This difference was said to be negligible, however, in their investigations because the ultraviolet radiant power of wave-lengths 2652 Å is less than .2 per cent of that of wave-length 2537 Å. The Council on Therapy stated that satisfactory evidence was not available to warrant acceptance of ultraviolet lamps for disinfecting solids. It was stated that the whole subject is too new, too complex, and apparently too uncertain where virulent microorganisms may be concerned. This statement would include application of ultraviolet radiation in meat-storage coolers, a much-exploited application today.

SPICES

Spices are interesting microbiologically for various reasons. They may harbor types which cause spoilage of foods to which they are added; efforts have been made to rid them of such microorganisms. Certain spices also show appreciable germicidal properties which give them a double function in foods.

182. J. Amer. Med. Assoc. 118 (1942), 298-299.

Germicidal Action of Spices. This is probably not a property of great significance in itself but perhaps important when superimposed on other methods of preservation. Bitting¹⁸³ found cinnamon and cloves to possess stronger bactericidal activity than other spices. Hoffman and Evans¹⁸⁴ and Bachmann,¹⁸⁵ in general, confirmed Bitting's work. Cinnamic aldehyde found in cinnamon and eugenol found in cloves were especially active. In a later paper Bachmann¹⁸⁵ and Grove¹⁸⁶ reported more confirmatory conclusions on these two spices.

Extracts of various substances which are used for improving flavor of foods have also been investigated. Morel and Rochaix¹⁸⁷ observed only feeble action of such products as extracts of thyme, bergamot, and lavender. They believed that they could not replace other established agents of preservation. Similar investigations were carried out by Corran and Edgar¹⁸⁸ with various spices, condiments, and herbs and their oils on the fermentation of beer wort by yeast at room temperature; ground mustard was the most effective preservative followed by cloves and cinnamon. The other spices tested showed little or no preserving action. Some of the substances used—thyme, bay leaves, marjoram, savory, and rosemary—appeared to stimulate yeast action; this was also true for black pepper. The volatile oil of mustard was the strongest preservative of the oils, followed by cinnamon oil and the oils of cloves, thyme, and bay leaves.

Fabian, Krehl, and Little's¹⁸⁹ work showed that cinnamon and cloves were the only spices that exhibited any inhibiting action on bacterial growth in low concentrations. Ground peppercorn and allspice showed inhibiting action in one-per cent concentrations; mustard, mace, nutmeg, and ginger, in five-per cent concentrations; and celery used in 10- and 20-per cent concentrations in nutrient agar, against a majority of bacteria. Some species grow on all concentrations of spices. Fabian and his colleagues observed a great difference in the resistance of different bacteria to the same spice and the same organism to different spices. *Staphylococcus aureus* was more susceptible to the action of spices than many of the bacteria examined. The oils of spices were more inhibitory than ground spices.

Germicidal Action of Condiments. These are seasonings which are widely used in foods. Their germicidal properties have been found to be appreciable. Crushed horse-radish vapors were found to be inhibitory by Foter and Golick.¹⁹⁰ Such test organisms as *Serratia marcescens*, *Bacillus subtilis*, *Escherichia coli*, *Mycobacterium phlei*, and *Mycobacterium tuberculosis* (hominis) were used. One-gram amounts of the material were placed in the tops of inverted Petri dishes, the bottoms of which contained 15 ml. of a suitable agar medium. The plates were sealed and incubated

at the different temperatures for varying lengths of time, after which the covers were replaced, the plates streaked with the test organisms, sealed, and incubated at 37.5°C. (99.5°F.). The inhibitory effects were most pronounced at 37.5°C. and decreased with the lowering of the temperature of exposure. *Bacillus subtilis* was the least resistant, *Escherichia coli* the most resistant of the test organisms. Growth of the test organisms was inhibited to some degree by an exposure as short as 16 minutes in all cases and at all temperatures used. The inhibitory substance emitted by one gram of horse-radish was almost exhausted after six hours of exposure at 37.5°C. Minchin¹⁹¹ attributed germicidal properties to garlic. This was also observed by Vollrath, Walton, and Lindegren¹⁹² who made the same observation for onions. The bactericidal substance in garlic has been shown to be allyl aldehyde. When an agar plate was exposed to freshly crushed garlic enough bactericidal substance was absorbed in 30 minutes to destroy *Escherichia coli*. The well-known sulfides responsible for the peculiar odor of garlic were found not responsible for its bactericidal activity. Vollrath *et al.* believed that acrolein might be the bactericide of garlic. It was found to have active bactericidal properties. On the other hand, Kitagawa and Amano¹⁹³ related the germicidal properties of garlic to unstable sulfur in the polysulfides produced from glucosides by enzyme action. About all that Böker¹⁹⁴ could do was to attribute this action to a volatile substance.

Oligodynamic Action of Metals in Food Preservation. Much work has been done in late years on the effect of metals on microorganisms. Nägeli,¹⁹⁵ who did some of the pioneer work used the term "oligodynamic" to express the action of heavy metals on bacteria. The term "oligodynamic" today signifies the sterilizing effect of very small amounts of certain metals. Silver has been most generally used, being brought into solution by electrolysis from silver electrodes. This method has been much studied for sterilizing water, with which it seems to have given some success. It has also been suggested for other fluids as well as for foodstuffs. Many investigators have reported that when an electric current is passed through thin silver plates in water the water becomes highly bactericidal. According to Metalniskoff,¹⁹⁶ a current as low as .3 to 4 milliamperes and 1.5 to 4.5 volts passed through water containing representative bacteria, such as *Escherichia coli*, *Vibrio cholerae*, *Salmonella paratyphi*, *Eberthella typhosus*, and *Staphylococcus aureus*, killed all of them in a few minutes and often in a few seconds when the silver plate is the anode. Boiling does not destroy the germicidal efficiency of the water so treated. This bactericidal power remains for more than three months. The concentration of germicide in the water can be increased by prolonged exposure to the current or increasing the plate surface. Silver in a concentration of 1/5,000,000

will kill *Escherichia coli* and staphylococci in three hours. Water does not become germicidal if the silver is the cathode.

In early work on the problem the silver ions were secured from sand grains which had been coated with silver. Heiss¹⁹⁷ reported that a piece of silver wire showed no bactericidal action unless a minute quantity of silver chloride or silver nitrate was placed on it. Then the whole length of wire became active. Fromherz and Heiss¹⁹⁷ stated that experimental evidence showed the oligodynamic action of silver to be due to silver ions in a concentration greater than 2×10^{-11} moles per liter. The silver ions either come directly from silver compounds, or are sent out by means of localized currents in concentration cells on superficially oxidized or impure silver parts.

A well-known method of getting silver into the water is the Katadyn process of Krause. In the first process, silver existed in the water as ionic silver. It was derived from sand grains coated with silver. The Electro-Katadyn process is so designed that silver is derived by passing on electric current between silver electrodes immersed in water. Perini¹⁹⁹ reported that silver ions in water exerted a bactericidal effect; he inoculated various foodstuffs with several members of the coliform group and then washed them with water containing silver. A contact time of from 20 to 30 minutes was sufficient to destroy pathogenic bacteria. Slavin²⁰⁰ could find no reason for using silver-treated water in the food industry. Herrmann²⁰¹ concurred in this opinion. Perini,¹⁹⁹ however, reported satisfactory results with fresh vegetables, oysters, and other foods. The process has been reviewed by Callister.²⁰²

Kufferath²⁰³ described briefly the development and uses of the Katadyn process in which silver ions are discharged into the water from silver electrodes by a weak current. It has the advantages that the amount of silver going into solution can be regulated by the strength of the current; large quantities of water can be treated; water with strong bactericidal power can be prepared so that the process can be used in ice making, in mineral-water factories, and in breweries; water containing suspended matter can be treated by increasing the amount of silver dissolved. The apparatus is simple in construction and wholly or partially automatic in action, and costs for current and silver are low. Oligodynamic power of silver was tested by Ruge²⁰⁴ on organisms of the coliform group and on staphylococcus by subjecting them to the action in various concentrations for varying lengths of time at room temperature. Efficient results in domestic or commercial sterilization of water with a simple Katadyn apparatus were reported.

Results of extensive studies on this problem were reported by Grimmer and Grenz²⁰⁵ on the effect of "Katadynized" water on lactobacilli, lactic acid streptococci, tetracocci, micrococci, sarcinae, on the colon-aerogenes, proteus and fluorescens groups, aerobic sporeformers, chromogenic cocci and bacilli, yeasts, and *Oospora* spores and molds, especially in connection with disinfection of churns. With a colloidal silver concentration of .65 microgram per liter of water, after four hours exposure, the total number of microorganisms in a churn rinse was reduced 20 per cent. Aerogenes, proteus, and fluorescens types were rapidly destroyed. Lactobacilli, lactic acid streptococci, and coliform types were sensitive to silver, while aerobic sporeformers, Sarcinae, and yeasts were scarcely affected and molds increased. Decreases were greater with higher concentrations of silver. In the churns the Katadyn water had no marked residual effect; it was necessary to use it regularly to obtain satisfactory results. Other studies were made to determine the effect of the activated water on the keeping quality and microflora of butter. The silver exerted a detrimental effect on keeping quality, with tallowy and oily flavors developing. The total number of microorganisms in butter was not appreciably lower at the end of the storage period than for butter washed with ordinary water. The lactic acid bacteria were most affected, while nonacid formers, yeasts, and molds increased.

The Katadyn process was not approved by Shapiro and Hale²⁰⁶ for swimming pools because bacteria growing at 37° C. (98.6° F.) are not affected; too much time is required; the treatment must be adjusted to individual waters; the presence of ammonia interferes with good results; there is no adequate method for determining the presence of silver; there is a question as to economy as compared with chloride, and there is the danger of the development of argyrosis.

Attempts have also been made to introduce this method into the food industry. Perini¹⁹⁹ inoculated various foodstuffs with bacterial cultures (*Escherichia coli*, *Eberthella typhosa*, *Salmonella paratyphi*, *Salmonella schottmülleri*, as well as *Vibrio comma*) and then subjected the foodstuffs to washing with the water containing silver ions. He showed that the washing of these substances in water which has been subjected to the Electro-Katadyn process suffices to kill pathogenic intestinal organisms with which the foodstuffs may have been affected. A contact time of 20 to 30 minutes is sufficient.

According to Mehltitz²⁰⁷ turbid must from pressed fruit or apple and grape juices previously clarified to a certain extent by decantation can be rendered stable by the Electro-Katadyn process with the use of a minimum of about 20,000 μg . per liter of silver. The process can be used with complete certainty in practice only with clear, filtered, and therefore slime-free juices low in bacteria. To make certain the products will keep for many months in this case at least about 5,000 μg . per liter of silver are required.

When well-cleaned glass containers are used, the walls of the container itself are found to be sterile after filling with the activated juices. Even after the germicidal action has disappeared, no bacterial life develops. With the use of 7,500 or more $\mu\text{g.}$ per liter of silver for activation, a definite metallic taste appears which, however, (even with 20,000 $\mu\text{g.}$) completely disappears after storage for several months. Activation with from 5,000 to 20,000 $\mu\text{g.}$ silver leaves the juice practically unchanged analytically. During storage the activating silver separates out continuously to a greater or less degree; with turbid juices, it separates completely. This precipitation process appears to be largely dependent upon the composition of the fruit juices. A modification of the method by Jendrassik²⁰⁸ is described for the determination of very small amounts of silver as the original method is unsuitable for use with musts. Two hundred milliliters of the must is fermented with yeast, evaporated to 20 to 25 ml., and oxidized with $\text{HNO}_3 + \text{H}_2\text{SO}_4$ according to more specific directions given in the original. The solution is then diluted with water, made ammoniacal, and the silver determined with p-dimethylaminobenzilidene thiocyanate.

As certain commercial organizations are recommending silver for use as a bactericidal and preserving agent, not only for water but also for a number of foodstuffs and beverages, Gibbard²⁰⁹ believed it desirable for public-health authorities to know whether the process is harmful to health and whether it is efficient. Experiments here recorded confirm the view of other workers that it is the silver ions, probably derived from silver oxide, which possess bactericidal action. This action is markedly reduced by the presence of proteins or of glucose. Grape juice purported to have been treated by a silver process did not contain silver in significant amount.

Enzymes in Foods. Practically all foods contain enzymes and it is important to learn what becomes of them after the food is harvested and stored or during processing. Balls^{209a} stated that preservation of food is a matter of stopping enzyme action, whether the enzymes come from microorganisms or are inherent in the food itself. Cold storage and drying slow down enzyme action but application of heat is the main method for destroying them. In view of this fact, foods which are processed by heat must be carefully and adequately heated. Unless most of the enzymes are destroyed, the foods must be stored either very dry or cold. The problem is not great with heat processed foods but is with frozen foods. In the latter enzymes may lead to untoward changes.

FOOD STANDARDS AND FOOD-CONTROL ACTS

These have been necessary since certain members of society took it upon themselves to prepare and sell foods to others. Some of them proved to be unscrupulous and sold food which was unfit for consumption. Food-control acts had to be established to control such practices. Probably the first effort along these lines was the code given to the Israelites by Moses.²¹⁰

210. The Bible. An American Translation, Book of Leviticus, Chapter 11; Book of Deuteronomy, Chapter 14.

In this respect Moses may be considered to be the first food inspector. He classed foods as either clean or unclean with a different meaning for those terms than they have today. Those which were to be eaten were said to be clean. The others were unclean. Such a separation was made on the basis of a natural abhorrence of certain species, a demonstrated unsuitableness, or on habits of prey. Probably bitter experience with certain foods caused Moses to place them on the prohibited list. Animals which ate carrion and blood were not accepted. A religious repugnance probably existed for serpents.

The following quotation from Deuteronomy, Chapter 14,²¹⁰ summarizes the statements of Moses with respect to foods:

"You must not eat anything abominable. The following are animals that you may eat: the ox, the sheep, the goat, the deer, the gazelle, the roebuck, the wild-goat, the ibex, the antelope, and the mountain-sheep: Also, you may eat any animal with a cloven hoof, that has the hoof divided completely in two, and that chews the cud. However, of those that chew the cud or have the hoof completely cloven, you must not eat the following: the camel, the hare, and the rockbadger, because, although chewing the cud, they do not have the hoof cloven—they are unclean for you; also the pig, because, although having the hoof cloven, it does not chew the cud—it is unclean for you. Of their flesh you must not eat, and their carcasses you must not touch.

"Of all things that live in the water you may eat the following: whatever has fins and scales you may eat; but whatever has not fins and scales you must not eat; it is unclean for you.

"You may eat any clean bird; but the following are the ones of which you must not eat: the griffon, the vulture, the eagle, the buzzard, the kite in its several species, the raven in all its species, the screech-owl, the eagle-owl, the horned owl, the jackdaw, the carrion-vulture, the cormorant, the stork, the heron in its several species, the bittern, and the bat. Also, all winged insects are unclean for you; they must not be eaten. Any winged thing that is clean you may eat.

"You must not eat anything that has died a natural death; for you are a people consecrated to the LORD your God; you may give it to any alien residing in your community to eat, or sell it to a foreigner."

Foods require inspection and control for many reasons, some of which are obscure. Not all of them are prepared and handled under conditions which keep them clean and safe until delivered to the consumer. In some cases health hazards are not involved while fraud and adulteration are. Manley²¹¹ pointed out, in this respect, the substitution of a cheaper for a more expensive food, such as incorporation of undue amounts of starch in certain meat products. He believed that high food standards were desirable, especially for compound foods. This subject was discussed by the Ministry of Health of Great Britain in its annual report for 1934.

Food control in Great Britain was said to rest upon two broad principles: first, fair trading, in the sense that the public buying food should have some guarantee that they are getting what they ask and pay for; and second, that the food shall not contain ingredients which will render it injurious to health. These are expressed in our own food and drug act as honesty and fair dealing.

With respect to the first principle, it was believed that little gross adulteration or deliberate substitution of one article of food for another

211. Manley. 1933. *J. Roy. San. Inst.* 54, 214-318.

occurred. The Minister did mention a sophistication of substitution of Ailanthus leaves for mint. He also reported a substitution which might not be construed to be an adulteration. Cakes, however, were colored brown as if they contained chocolate when no chocolate was used in their preparation. In some cases it was said to be very difficult for a purchaser to judge the quality of food which had been skillfully prepared, packed, and advertised for sale. In an earlier annual report the Ministry of Health called attention to the fact that employment of chemists and other scientists by food purveyors has greatly complicated the situation for control officials. Every effort should be made to compel those who speak about their products to give nothing but the absolute truth; for instance, the Minister mentioned the advertising of a margarine as being blended with butter, whereas in reality it contained only one-half per cent butter.

As a general rule standards of quality were deemed necessary although in some cases it might be difficult to determine them. It was suggested that careful descriptive labeling be required to protect the consumer.²¹² This has been attempted in the United States in the Food, Drug, and Cosmetic Act of 1938.

The second principle that foods shall not contain any ingredients which will render them injurious to health could be defined more strictly. The Food and Drug Act forbids addition of such ingredients to foods but it is difficult to determine whether added substances are deleterious to health. It was pointed out that it is almost impossible for anyone to decide with respect to the amount of copper, for instance, which may be considered negligible in foods. This is due to the fact that the factors which contribute to daily health and well-being of individuals are numerous and very complex. Furthermore, it would require a well-balanced, thorough laboratory investigation to prove the situation. Consequently the Ministry of Health believed that the safest course was to limit the amount of some substances in question to the smallest that can be achieved in practice. This was said to have been the course adopted by the Commission on Arsenical Poisoning in 1903. They found that it was possible for manufacturers to keep the amount of arsenic in food below 1/100 grain per pound. Therefore, the Commission recommended this limit, not because it had any definite relation to the dose required to produce arsenical neuritis but because it was a limit which could be achieved without hardship to the manufacturer and appeared to provide a satisfactory margin of safety to the consumer. It was stated that the same considerations were taken into account in the regulations of 1925 dealing with the addition of chemical preservatives to food. It aids in fixing the amounts of unavoidable impurities at low amounts which could be achieved by competent manufacturers. The Ministry of Health said that a number of other varied problems awaited the food manufacturer. He mentioned, for instance, the increasing use of ethylene glycol as a solvent for essences.

212. Report of the Chief Medical Officer of the Ministry of Health for Year the 1934. (1935) 122-125.

The United States Food and Drug Act of 1906. This was the first effort in the United States to control quality of food. It resulted from much agitation on the part of food-control officials and those who realized the need for control. The Dominion of Canada passed a similar act respecting food and drugs in 1920. The United States Food and Drug Act aims to prevent the misbranding and adulteration of foods and drugs. As used in the Act, the term "food" includes all articles used for food, drink, confectionery, or condiment by man or other animals, whether simple, mixed, or compound. In the case of food it is considered as "adulterated" under the Act if:

1. Any substance has been mixed and packed with it so as to reduce or lower or injuriously affect its quality or strength.
2. Any substance had been substituted wholly or in part for the article.
3. Any valuable constituent of the article has been wholly or in part abstracted.
4. It be mixed, colored, powdered, coated, or stained in a manner whereby damage or inferiority is concealed.
5. It contain any added poisonous or other added deleterious ingredient which may render such article injurious to health; Provided, That when in the preparation of food products for shipment they are preserved by an external application applied in such manner that the preservative is necessarily removed mechanically, or by maceration in water, or otherwise, and directions for the removal of said preservative shall be printed on the covering or the package, the provisions of this act shall be construed as applying only when said products are ready for consumption.
6. It consist in whole or in part of a filthy, decomposed, or putrid animal or vegetable substance, or any portion of an animal unfit for food, whether manufactured or not, or if it is the product of a diseased animal, or one that has died otherwise than by slaughter.

Control of food products in the United States is centered in the various bureaus and administrations of the United States Department of Agriculture. The Food, Drug, and Insecticide Administration has jurisdiction over foods distributed in interstate commerce and the enforcement of the Food and Drug Act. Thom⁶⁵ called attention to the fact that the Food and Drug Act of 1906 is a corrective rather than punitive measure.

The United States Food, Drug, and Cosmetic Act of 1938. After some five years of consideration in Congress, President F. D. Roosevelt signed the Food, Drug, and Cosmetic Act on June 25, 1938. Several bills were proposed and debated at length before a satisfactory bill was proposed. The old Food and Drug Act of 1906 was automatically repealed with minor exceptions. The new act greatly extended the definitions of adulteration and misbranding of foodstuffs. That part of the act which concerns foods is quoted below:

ADULTERATED FOOD

"SEC. 402. A food shall be deemed to be adulterated

"(a) (1) If it bears or contains any poisonous or deleterious substance which may render it injurious to health; but in case the substance is not an added substance such food shall not be considered adulterated under this clause if the quantity of such substance in such food does not ordinarily render it injurious to health; or (2) if it bears or contains any added poisonous or added deleterious substance which is unsafe within the meaning of section 406; or (3) if it consists in whole or in part of any filthy, putrid, or decomposed substance, or if it is otherwise unfit for food; or (4) if it has been prepared, packed, or held under insanitary conditions whereby it may have

become contaminated with filth, or whereby it may have been rendered injurious to health; or (5) if it is, in whole or in part, the product of a diseased animal or of an animal which has died otherwise than by slaughter; or (6) if its container is composed, in whole or in part, of any poisonous or deleterious substance which may render the contents injurious to health.

"(b) (1) If any valuable constituent has been in whole or in part omitted or abstracted therefrom; or (2) if any substance has been substituted wholly or in part therefor; or (3) if damage or inferiority has been concealed in any manner; or (4) if any substance has been added thereto or mixed or packed therewith so as to increase its bulk or weight, or reduce its quality or strength, or make it appear better or of greater value than it is.

"(c) If it bears or contains a coal-tar color other than one from a batch that has been certified in accordance with regulations as provided by section 406; *Provided*, That this paragraph shall not apply to citrus fruit bearing or containing a coal-tar color if application for listing of such color has been made under this Act and such application has not been acted on by the Secretary, if such color was commonly used prior to the enactment of this Act for the purpose of coloring citrus fruit.

"(d) If it is a confectionery, and it bears or contains any alcohol or nonnutritive article or substance except harmless coloring, harmless flavoring, harmless resinous glaze not in excess of four-tenths of 1 per centum, natural gum, and pectin: *Provided*, That this paragraph shall not apply to any confectionery by reason of its containing less than one-half of 1 per centum by volume of alcohol derived solely from the use of flavoring extracts, or to any chewing gum by reason of its containing harmless nonnutritive masticatory substances."

MISBRANDED FOOD

This provision of the Food, Drug, and Cosmetic Act of 1938 concerns mainly the element of fair dealing in transactions involving foods. Violation of it may not necessarily be injurious to health. Section 403 states that a food shall be deemed to be misbranded:

"(a) If its labeling is false or misleading in any particular.

"(b) If it is offered for sale under the name of another food.

"(c) If it is an imitation of another food, unless its label bears, in type of uniform size and prominence, the word 'imitation' and, immediately thereafter, the name of the food imitated.

"(d) If its container is so made, formed, or filled as to be misleading.

"(e) If in package form unless it bears a label containing (1) the name and place of business of the manufacturer, packer, or distributor; and (2) an accurate statement of the quantity of the contents in terms of weight, measure, or numerical count: *Provided*, That under clause (2) of this paragraph reasonable variations shall be permitted, and exemptions as to small packages shall be established, by regulations prescribed by the Secretary.

"(f) If any word, statement, or other information required by or under authority of this Act to appear on the label or labeling is not prominently placed thereon with such conspicuousness (as compared with other words, statements, designs, or devices, in the labeling) and in such terms as to render it likely to be read and understood by the ordinary individual under customary conditions of purchase and use.

"(g) If it purports to be or is represented as a food for which a definition and standard of identity has been prescribed by regulations as provided by section 401, unless (1) it conforms to such definition and standard, and (2) its label bears the name of the food specified in the definition and standard, and, insofar as may be required by such regulations, the common names of optional ingredients (other than spices, flavoring, and coloring) present in such food.

"(h) If it purports to be or is represented as—

"(1) a food for which a standard of quality has been prescribed by regulations as provided by section 401, and its quality falls below such standard, unless its label

bears, in such manner and form as such regulations specify, a statement that it falls below such standard; or

"(2) a food for which a standard or standards of fill of container have been prescribed by regulations as provided by section 401, and it falls below the standard of fill of container applicable thereto, unless its label bears, in such manner and form as such regulations specify, a statement that it falls below such standard.

"(i) If it is not subject to the provisions of paragraph (g) of this section unless its label bears (1) the common or usual name of the food, if any there be, and (2) in case it is fabricated from two or more ingredients, the common or usual name of each such ingredient; except that spices, flavorings, and colorings, other than those sold as such, may be designated as spices, flavorings, and colorings without naming each: *Provided*, That, to the extent that compliance with the requirements of clause (2) of this paragraph is impracticable, or results in deception or unfair competition, exemptions shall be established by regulations promulgated by the Secretary.

"(j) If it purports to be or is represented for special dietary uses, unless its label bears such information concerning its vitamin, mineral, and other dietary properties as the Secretary determines to be, and by regulations prescribes as necessary in order fully to inform purchasers as to its value for such uses.

"(k) If it bears or contains any artificial flavoring, artificial coloring, or chemical preservative, unless it bears labeling stating that fact: *Provided*, That to the extent that compliance with the requirements of this paragraph is impracticable, exemptions shall be established by regulations promulgated by the Secretary. The provisions of this paragraph and paragraphs (g) and (i) with respect to artificial coloring shall not apply in the case of butter, cheese, or ice cream."

The food and drug law which became effective June 25, 1939, contains the better features of the old act and many new ones which changes in modern life made necessary.²¹³ Greater power is given the government to control foods and drugs. The Secretary of Agriculture is authorized to promulgate definitions and standards. The new act according to Dunbar²¹⁴ preserves all of the valuable features of the older one of 1906 and includes valuable new ones.

One difficulty which food processors face is contamination of the food after it leaves their warehouse. Through ignorance and carelessness, all the good results of technical service in the factory may be negated by improper handling by the retailer or in the consumer's kitchen. Examples of this are food-poisoning cases which have resulted from eating smoked sausage packed in oil. In most of these cases, contamination of the food after opening in the retailer's store was indicated.

Definitions and Standards for Food. These are necessary for use of food-control officials. They must have an acceptable definition of a food in order to know whether foods which they investigate on the market are satisfactory. Definitions and standards for food are provided for in the Food, Drug, and Cosmetic Act of 1938. Sec. 401 reads as follows:

"Whenever in the judgment of the Secretary such action will promote honesty and fair dealing in the interest of consumers, he shall promulgate regulations fixing and establishing for any food, under its common or usual name so far as practicable, a reasonable definition and standard of identity, a reasonable standard of quality, and/or reasonable standards of fill of container: . . . In prescribing a definition and standard of identity for any food or class of food in which optional ingredients are permitted,

213. Hubbard. 1938. *Modern Brewer* 20, 38-40.

214. Dunbar. 1939. *News Edition, Ind. Eng. Chem.* 17, 225-227.

the Secretary shall, for the purpose of promoting honesty and fair dealing in the interest of consumers, designate the optional ingredients which shall be named on the label . . ."

Public hearings are held at which any interested person may present his views. The evidence thus recorded is used as a basis for whatever rulings are made by the Administrator.

WRAPPING AND PACKAGING OF FOODS

Proper wrapping and packaging is an integral part of making high-grade foods available to the public. Unless they are distributed from the processing plant to the consumer under proper conditions quality and safety may not be maintained. Food products distributed by American vendors are, in general, wrapped or packaged in the place where they are processed. The food itself is not handled by anyone until it is prepared for the table. Tin and glass containers and paper and paper board in various forms have been used largely to attain this ideal situation. The former are discussed later in the chapter on canning.

Many questions have to be considered and the wrapper must always be considered in relation to the foodstuff to be wrapped. Points to be considered are strength, permeability to moisture, actual waterproof qualities, liability of odors, addition of harmful substances from the wrappers, such as poisonous metals or preservatives, effect on rancidity production (for fatty foods), and price. Moisture-vapor-proof wrappings are liable to cause odors to be developed. Foods may be contaminated with formaldehyde if packed in transparent wrappings of gelatin hardened with it. Tin, lead, and even arsenic may be added to foods from wrappers in poisonous amounts. Cheese packed in tinfoil has been found to contain up to 23,000 p.p.m. of tin, the usual permitted limit being 287 parts per million. Permeability to light affects rancidity, and wrappers only permeable to certain light wave lengths which are inoperative in these matters have been placed on the market.²¹⁵

Besides these possibilities are those involving microorganisms which have been carefully considered in the chapter on milk under the discussion of the milk bottle.

Paper Containers and Wrappings for Foods. Paper has played an important role for decades in storage and shipment of foods. Despite the fact that other materials have been used for this purpose, treated paper seems to have made a distinct place of its own. Paper containers and wrappings have one distinct advantage over those made of other materials in that they are used but once. They do not present, therefore, the sanitary hazards which are inherent in containers used over and over again. That sanitary hazards exist for the latter is evidenced by regulations of many health departments prohibiting removal of milk bottles from homes in which there is a case of communicable disease.

Cleaning and sterilization of multi-use containers present problems which have not been easily solved. Many committees of various organiza-

tions have discussed the problems involved in cleaning and sterilizing the glass milk bottle. Carbonated beverage bottles are also in this same category. Such problems as these would be solved if containers could be developed which could be discarded after use.

Little worry need be caused by the fact that some paperboard containers are made from paper which has been used once. This material is subjected in the paper mill to several processes which greatly reduce its content of microorganisms and destroy pathogenic bacteria. These processes include cooking at high temperatures, bleaching with chlorine, and drying on rolls at high temperatures on the papermaking machines.

Much paper and paperboard is paraffined for various reasons given by Tanner and Lewis.²¹⁶ More recently the germicidal properties of this treatment of paper have become important for the single-service paper milk container.

Methods for Bacteriological Examination of Paper. These are only of relatively recent origin. Such procedures involve disintegration of the paper or paperboard to a thin homogeneous suspension of fiber which is then plated and cultured in various culture media. A procedure was published in 1940 by the Technical Association of the Pulp and Paper Industry.²¹⁷

Another procedure for determining the bacterial content of paper, outlined by Cartwright and Epstein²¹⁸ will not be presented here. The great problem is to determine what results of a technic just presented mean. The high temperatures attained in cooking the pulp, the heavy chlorination to bleach it, and finally, the temperature on the drying rolls are lethal agents of known efficiency. Experiments have shown that pathogenic bacteria cannot survive on drying rolls.

The Food Investigation Board of Great Britain²¹⁹ has found that wrapping individual units of fruits is beneficial. The wrappers are impregnated with various substances which either inhibit microorganisms or destroy them. The first work was done by soaking the wrappers in odorless mineral oil. Tomkins²²⁰ found iodized wrappers to reduce rotting of fruits, which prompted him to experiment with other possible chemical substances. Among the many which were studied, diphenyl, in addition to iodine, was found to be usable. Use of wrappers treated with such substances function in reducing rot by mechanically restricting the spores of rot-producing fungi as well as by destroying them. Ortho-phenylphenol to the extent of 8.7 to 23.3 mg. per square foot in wrappers was found by Van der Plank and Rattray²²¹ to reduce decay of stored lemons. Glyceride oil, such as olive oil, retarded fruit injury caused by ortho-phenylphenol.

CHAPTER 2

THE BACTERIA

Food microbiologists frequently find it necessary to determine certain characteristics of an organism if not characterize it completely. This is especially true for those which cause spoilage or which may have some special role such as those in butter cultures. Some confusion has always existed in classification and nomenclature of microorganisms. This has led to duplication of names and diversity of characteristics for the same organism.¹ Winslow,² recognizing the difficulties of such a situation, appealed for careful preservation of original types so that future investigators could have the type species for study. This is of great importance in microbiology of foods.

The Descriptive Chart of the Society of American Bacteriologists. The Descriptive Chart³ of the Society of American Bacteriologists is the result of years of effort to secure a concise means of recording characteristics of microorganisms. Harding⁴ reviewed the earlier contributions. Johnston,⁵ Harding and Prucha,⁶ Conn,⁷ and others have used the chart in the study of several of the more common groups of bacteria. The value of the chart is especially apparent in the study of many closely related strains or in the study of the flora of a particular material, such as canned corn, pasteurized milk, and similar foods.

Procedure for Studying Characteristics of Bacteria. Failure to use comparable methods for determining the characteristics of bacteria has often resulted in confusion and conflicting opinions about the characteristics of bacteria. In order to remedy this situation and to insure availability of suitable methods, the Society of American Bacteriologists appointed a committee to study bacteriological technic. Under the direction of Dr. H. J. Conn, of the Agricultural Experiment Station, Geneva, New York, *A Manual of Methods for Pure Culture Study of Bacteria* was published.⁸ This manual contains recommended procedures for characterizing bacteria and has helped to bring some order into a confused situation.

Media. The importance of using carefully prepared media needs emphasis. All media should be prepared according to recognized authority such as the Standard Methods of the American Public Health Association. This organization has two reports of such a nature: *Standard Methods for the Examination of Dairy Products* was prepared in collaboration with the Association of Official Agricultural Chemists; a new edition of *Stan-*

1. The details of elementary technic may be found in the author's "Practical Bacteriology," published by John Wiley & Sons, Inc., New York City, 1928.

8. Copies of this pamphlet, as well as the Descriptive Chart mentioned above, may be secured from Dr. H. J. Conn, Agricultural Experiment Station, Geneva, N. Y.

Standard Methods for the Examination of Water is published about every five years. Both of these reports should be in every laboratory concerned with food microbiology. *Manual of Methods for Pure Culture Study of Bacteria*⁸ also contains information about media. A large number of formulas for media useful in food bacteriology are given in Chapter 26 of this book.

Media should always be incubated before use to make certain that they are sterile. Especially is this true when studying thermophilic bacteria or other heat-resistant species. Such media should be tested at 55°C. (131°F.) for the colonies of many thermophiles will not appear at 37°C. (98.6°F.). Their spores are resistant to heat and many survive sterilization methods which are adequate for mesophilic species. Spores of *Clostridium botulinum* are also especially heat resistant.

Motility. Some care is necessary in interpreting results of motility determinations. Positive results are probably satisfactory, but negative results are convincing only after a number of attempts. The safest method is to make flagella stains, for if the organism possesses flagella, it is reasonable to assume that it is motile. Various procedures for flagella staining are given under "Staining Reactions" in a paragraph to follow. Sturges⁹ stated that flattened capillary tubes made excellent cells for examination of bacteria. Filled with drops of broth cultures and sealed off, these cells may be used for observations on motility.

Carnot and Halle's¹⁰ Method for Determining Motility. These investigators devised a unique method for determining the rate of motion exhibited by an organism. The method has been adapted to isolating the motile *Eberthella typhosa* from water. A U-shaped tube into which are placed sterile bouillon, sand, and the material under examination, or in pure culture work a broth culture of the bacterium whose motility is under study, is used. Bacteria which are motile will propel themselves through the sand layer in a given time. By establishing standard arbitrary conditions, the relative motility of an organism may be found.

Procedure. Draw out a seven-mm. piece of glass tubing in a flame and then bend to make the Carnot and Garnier U-tube. Each limb of this tube should have a length of about 25 cm. A small amount of glass wool should be forced down into the larger arm. Sterile broth is then poured into the larger tube until about 10 cm. of the limbs of the tube are filled. Into the large tube should then be poured sufficient purified sand thoroughly washed in acid and sterilized to come up to between 10 or 15 cm. The pure culture of the organism whose motility is under study is inoculated into the broth of the smaller arm. If the tube is incubated at the optimum temperature, the time for passage through the sand may thus be determined. According to Carnot and Garnier *Microspira cholerae* passed through one inch of sand in one hour and 38 minutes. Cloudiness in the uninoculated arm is the index of the organism's presence. Gautier¹¹ and Levy¹² used the sand tube with success for isolating motile organisms.

STAINING REACTIONS

To make a complete study of the staining properties of an organism all of the stains mentioned on the Descriptive Chart should be used. Common special stains, such as the acid-fast should also be tried. Pro-

cedures for staining microorganisms have been given in several places in this book. Supplement A (entitled Staining Procedures) to the *Manual of Methods for Pure Culture Study of Bacteria* contains a compilation of useful methods. This should be available to all food bacteriologists.

Staining of Flagella. This has been a difficult procedure for many bacteriologists. It may be due to lack of care in some of the preparatory procedures. Smith¹³ has mentioned some of the common errors:

1. Oily or otherwise dirty cover glasses.
2. Unsuitable cultures.
3. Breaking off the flagella.
4. Uneven or too copious distribution of the bacteria.
5. Imperfect mordanting.
6. Understaining or overstaining.
7. Precipitates on the cover glass during some stage of the process.

The greatest error probably lies in dirty slides and cover glasses. These should be cleaned in strong alkali, in order to saponify any animal grease which may be on them, and thoroughly rinsed. Otherwise, the film will "roll" and not spread evenly. The culture which is stained must be young and vigorous. A small amount of this growth should be transferred to a test tube of sterile water and incubated at 37°C.(98.6°F.). After several hours, some of this suspension should be put on slides and allowed to dry by placing the slides in the 37°C. incubator. The film should then be fixed and stained.

The author has secured the best results with Loeffler's and Plimmer and Paine's methods. A double boiler is prepared from two beakers. The inner is supported by pieces of cork. The staining solution should be put into the inner one and the temperature raised to about 65°C.(149°F.) or until the stain steams. The slides are immersed in this solution and stained as long as required.

Loeffler's Flagella Stain.

LOEFFLER'S MORDANT.

Tannic acid, 20 per cent aqueous.....	10 ml.
Ferrous sulfate, saturated aqueous.....	5 ml.
Basic fuchsin, saturated alcoholic.....	1 ml.
Mix and filter after a short time.	

LOEFFLER'S STAIN.

Carbolic acid	20.0 ml.
Basic fuchsin, saturated alcoholic.....	2.5 ml.

After the film has been prepared it should be covered with the mordant and heated for two minutes. Wash in tap water and cover with the stain. Heat for two minutes as before. Wash, dry, and mount.

Plimmer and Paine's¹⁴ Modification of the Cesares-Gil Method for Staining Bacterial Flagella. Plimmer and Paine have proposed the following method:

The following ingredients are employed in making up the stain:

Tannic acid	10.0 grams
Aluminum chloride (hydrated).....	18.0 grams
Zinc chloride	10.0 grams
Rosaniline hydrochloride	1.5 grams
Alcohol, 60 per cent.....	40.0 ml.

13. Smith. 1905. Smithsonian Inst., Washington, D. C.

14. Plimmer and Paine. 1921. J. Path. & Bact. 24, 286-288.

Place the solids in a mortar, add 10 ml. of the alcohol and mix thoroughly, taking care to smash up all the zinc chloride. Stir in the rest of the alcohol slowly. At this point the mass goes gradually into a viscous solution of a deep red color, and in this state appears to remain stable for several years. For use, dilute with water, one part stain to four of water; when nearly complete precipitation occurs, a small amount remaining in solution as a balanced colloid.

Method of application:

1. The culture must be 18-24 hours old and must be removed carefully. Slides should be cleaned with chromic acid, and all grease removed by roasting them over a Bunsen burner. When they have cooled to blood heat, a small drop of the bacterial suspension is placed at one end, the slide tilted, and the drop allowed to run down, or it may be smeared gently with a strip of gutta-percha tissue. Quick drying of the film seems to be important, hence the warm slide. No fixing is required.

2. Apply the diluted mordant, allowing it to stand one minute after mixing with water. Filter into the slide and allow to stand for one minute, when a slight surface bronzing should be visible. Wash rapidly under the tap.

3. Flood the film with cold carbol fuchsin for five minutes, wash, dry, and examine in oil. If satisfactory, mount in balsam or euparal.

The advantages claimed for this method are the following:

1. The ease with which successful preparations are obtained makes it a useful stain in the hands of inexperienced students.

2. It is possible to have the background absolutely free from stain.

3. The flagella are uniformly stained without the appearance of granular deposits, and do not appear to be unduly magnified.

4. The mordant is a one-solution stain, seems to keep indefinitely in a well-stoppered bottle, and is always ready for use.

5. The materials are relatively cheap, as compared with other methods using osmic acid as a fixative.

Thatcher¹⁵ reported better preparations when the mordant was diluted with an equal amount of water. In the author's laboratory this has not been the case.

Conn and Wolfe¹⁶ raised the question whether the flagella stain could be made simple enough to be used as a routine test in studying pure cultures of bacteria. Motility as determined under the microscope in hanging drops, yields the first information on the presence or absence of flagella. They found the Gray¹⁷ procedure to give consistent results even in the hands of inexperienced technicians.

Gray's¹⁷ Flagella Stain as Modified by Conn and Wolfe.¹⁶ Conn and Wolfe hoped to develop a procedure which could be used in place of the test for motility. Despite the fact that flagella staining methods have been quite complicated and have often yielded erratic results, a modified Gray procedure was recommended for even inexperienced workers. The procedure is as follows:

Preparation of Glass Slides. Use new slides if possible. (This is because under the drastic method of cleaning to remove grease, old slides have a greater tendency to break, owing to crystallization of the glass.) Clean first in a dichromate cleaning fluid, wash in water, and rinse in 95 per cent alcohol; then wipe with a clean piece of cheesecloth. (Wiping is not always necessary but is advisable unless fresh alcohol is used after every few slides.) Pass each slide back and forth through a flame for some time, ordinarily until the appearance of an orange color in the flame; some experience is necessary before the proper amount of heating can be accurately judged.

Cool slides gradually in order to reanneal, and thus to minimize breakage. A crude but ordinarily satisfactory method of annealing is to place the flamed slides on a metal plate (flamed side up) standing on a vessel of boiling water; and then to remove the

15. Thatcher. 1927. *J. Stain Tech.* 1, 143.

16. Conn and Wolfe. 1938. *J. Bact.* 36, 517-520.

17. Gray. 1929. *Idem* 12, 273-274.

flame under the water so as to allow gradual cooling. (Failure to anneal may result in breakage, sometimes as long as two weeks after the heating.)

Preparation of Suspensions. Use young and actively growing cultures (e.g., 18 to 22 hours old), on agar slants. With a flamed *but well-cooled* loop, transfer a small amount of growth to five or 10 ml. of sterile distilled water, which has been held for several hours at room temperature. (Poor slides result from suspensions made in water that is too hot or too cold.)

Mix thoroughly in the distilled water and allow to stand five to 30 minutes, according to the type of growth produced. Gum-forming bacteria require 30 minutes, as recommended by Hofer and Wilson; those that produce no gum must stand in the water only five to 10 minutes. Standing in the water should be just long enough to allow the flagella to become untangled; too long a time results in their breaking off.

With a loop that has been flamed *and cooled*, remove a drop from the top of the suspension and place it on a glass slide prepared as above described. (The reason for taking material from near the surface of the suspension is because the nonmotile cells tend to settle, while the motile cells—at least in the case of aerobes—collect at the top.) Smear the drop over the slide with the use of a second slide, as in preparing blood films; the film should be thin enough to dry rapidly and thus to minimize distortion.

Staining. Use the mordant recommended by Gray: 5 ml. saturated aqueous solution potassium alum; 2 ml. saturated aqueous solution mercuric chloride; 2 ml. 20 per cent aqueous solution tannic acid; .4 ml. saturated alcoholic solution basic fuchsin (presumably about six per cent, which was the strength employed by Conn and Wolfe). For best results, filter just before using. The technic is essentially that of Gray. Apply cold for eight to 10 minutes; 10 minutes is ordinarily best, but this varies with the organism studied. (More than 10 minutes of mordanting is apt to cause too much precipitate.)

After mordanting, wash slides about 10 seconds in running water. Dry in the air, without heating. Stain five minutes, without heating, with Ziehl's carbol fuchsin; wash in running water; dry and examine.

Tittsler and Sandholzer¹⁸ suggested use of semisolid agar medium, results from use of which are macroscopic, thus obviating use of hanging drops. Motility was manifested by a diffuse zone of growth spreading from the line of inoculation. Conn and Wolfe said that this test picked out many organisms as motile which would not appear to be motile under the microscope.

Capsules. Several methods are available for demonstrating capsules. One method may supplement another and make results more convincing.

Consistency of Growth in Common Media. Capsulated bacteria usually grow with a slimy, sticky growth on common media. When touched with a sterile needle, it will pull out into threads.

Ordinary Aqueous-Alcoholic Stains. Films of capsulated bacteria when stained with ordinary aqueous-alcoholic stains, will show the bacteria with halos about the cells. These halos are capsules which have resisted penetration of the dye.

Special Staining Procedures. Special staining procedures for staining capsules are given below. These should be employed in research work to confirm evidence secured by other methods.

The Gins Method of Demonstrating Capsules. Hagan¹⁹ has called attention to the value of the Gins method for demonstration of capsules. The procedure, which involves staining of India-ink films of bacteria, is as follows (after Hagan):

18. Tittsler and Sandholzer. 1936. J. Bact. 31, 575-580.

19. Hagan. 1927. Science 66, 173.

1. Dilute the ink with an equal amount of sterile water, or dilute and sterilize.
2. Place a drop of the ink near one end of a very clean slide and carefully mix in a loopful of the bacterial suspension.
3. Then spread the mixture across the slide with the edge of a second slide. A properly prepared specimen should be uniformly spread and of a grayish color rather than black. (Films that are too thick may loosen after fixation.)
4. After drying in the air, fix the film with heat or by dipping in methyl alcohol.
5. Stain with an ordinary bacteriological stain. Microscopic examination will reveal well-stained bacteria lying in lacunae in the film of ink. The margin of the capsule is sharply delineated by the ink and the margin of the cells by the stain.

This is a very satisfactory method.

Endospores. Two methods are available. One involves the use of stains while the other is a heat test.

Ordinary Aqueous-Alcoholic Stains. Films may be stained with ordinary aqueous-alcoholic stains. The vegetative protoplasm (vegetative cells) will take the stain while the spores will resist and appear as colorless or very faintly colored units. Several different methods have been suggested at various times for staining bacteria.

Neisser's Method. Flood the smear with hot aniline fuchsin for about an hour. Wash in water and decolorize with acid alcohol (one part HCl and three parts alcohol). Too long decolorization may remove the stain from the spores also. Counterstain with methylene blue if desired.

- May's²⁰ Method.**
1. Make a film and fix in the usual manner.
 2. Cover with a small amount of five per cent chromic acid.
 3. After 30 seconds add about twice as much concentrated ammonia as there is chromic acid on the slide. Allow to act about two minutes.
 4. Rinse with tap water.
 5. Steam with carbol fuchsin for two or three minutes.
 6. Rinse.
 7. Restain with one per cent sulfuric acid for 15 to 30 seconds.
 8. Rinse again and flood the slide with tap water.
 9. Add to this a few drops of Loeffler's methylene blue and allow to stain for 10 to 30 seconds.
 10. Rinse, blot, dry, and examine.

Dorner's²¹ Method for Demonstrating Spores. This method which combines vital staining and a dark background is quite satisfactory. A heavy suspension of cells should be made in a small amount of water. To this suspension an equal amount of Ziehl-Nielsen carbol fuchsin solution is added and the mixture heated at 100°C. (212°F.) 10 to 15 minutes. A mixture of this stained suspension with an equal amount of nigrosin solution (five to 10 per cent) is made on a cover glass. This is then spread as thinly as possible and dried. Dorner later suggested addition of formalin as a preservative.

Schaeffer and Fulton's²² Method for Staining Endospores. This proposed procedure was said by the authors to be superior to other methods, such as those of Wirtz,²³ Hansen,²⁴ and Möeller.²⁵ The technic is as follows:

Make films in the usual manner and fix by flaming three times. Flood with malachite green solution (five per cent aqueous solution) and heat to steaming three or four times within one-half minute. Wash off the excess stain under the tap for about one-half minute. Apply a .5 per cent aqueous safranin solution one-half minute. Wash, blot, dry, and examine. This procedure is evidently more simple than the original method. The whole staining time involved is less than two minutes, and a minimum of steaming is required. Within wide limits it is impossible to overstain or wash too long.

24. Hansen. Cited from Schaeffer and Fulton.

25. Moeller. Idem.

Gray's²⁶ Method for Differential Staining of Spores and Vegetative Cells of Microorganisms. A solution for staining differentially spores and vegetative cytoplasm of bacteria, yeasts, and certain fungi was developed by Gray. Two forms of the solution have been developed—an aqueous concentrated solution and a saline dilution prepared from that.

Solution A. The Aqueous Concentrated Solution.

The solution is composed of the following amounts of the dyes in distilled water:

Malachite green	0.05 per cent
Fuchsin, basic	0.05 per cent

It has been found convenient to prepare separate solutions of the two dyes, in double strength; solution may be hastened by placing the containers in a water bath at 56°C. (132.8°F.); equal volumes of these solutions are mixed to obtain the staining solution with the dyes in the proportions stated. The staining solution appears to be stable. It should be noted that as there may be differences in dye content in dyes of different manufacture, or in different batches from a factory, a slight modification in quantities may be necessary. The malachite green used in this laboratory was supplied by the British Drug Houses, Limited, Toronto; the basic fuchsin by Coleman and Bell.

Solution B. The Saline, Diluted Solution.

This is prepared by diluting two parts of solution A with eight parts of an .8 per cent sodium chloride solution. This mode of dilution was adopted since it was found that dilution of the aqueous, concentrated solution with water, or 10 per cent glycerine solution, rapidly altered the cellular contents of the fungi used.

METHOD OF STAINING

The solution is allowed to act on fixed films for three or four minutes at room temperature; excess of stain is then washed off in running water, the film dried, and examined under the oil immersion objective. Spores in the early stage of development stain blue, in older stages, greenish-blue; ripe spores within the cell are tinged greenish-blue; free spores are unstained; the cytoplasm of vegetative cells stains violet in young cells, light violet in older cells, in some species pink rather than light violet.

Another simple method is to mix the cells in a loopful of the solution, on a slide, and allow it to dry. Fixing does not appear to be necessary. The excess of dry stain is washed off. The differentiation by this method is not as clear-cut as it is by the method described above.

By staining over steam, or by heating in a flame until steam rises, a sharper differentiation is obtained. The method adopted for heating has been to place the slide, with the stain on the film, on a 100-ml. beaker containing a little water; as soon as the water boils the flame is removed and the heating continued for one minute, though less may be all that is required; the slide is then cooled, washed, and dried. By this method (with solution A) the young spores may be masked by excess of violet; this may be removed by washing for a few seconds with 95-per cent ethyl alcohol, or by covering the film with a thin layer of a sterile two per cent solution of nigrosin. A loopful of the nigrosin is placed near the film after it has been stained, washed, and dried; by means of a strip of unsized (letterhead) paper, measuring one-half inch wide by one and one-half inches long, it is drawn with firm pressure and rapid movement over the film on which it thus dries quickly. The nigrosin (which is not recommended for films that have been stained with the saline solution) is useful to demonstrate "capsules" in young cultures in which spores have begun to develop; these have been found in *Bacillus megatherium*. It has been found that broth is a better medium than water for preparing suspensions of this organism, which tends to "clump" in water. Most of the violet color is removed by the nigrosin but the spores are left stained.

Heat-Resistance Test for Demonstrating Bacterial Spores. Bacterial spores are heat resistant, a characteristic which may be used for demon-

strating them in unknown cultures. If viable cells survive exposure to heat at 80°C. (176°F.) for 30 minutes it may be assumed that the organism is a sporeformer. A longer period of heating must be used for thermophilic bacteria. They should be heated for five or 10 minutes at 100°C. (212°F.).

The Gram Stain. The Gram stain must be carried out according to standard technic, if comparable results are to be secured. That the procedure is not entirely satisfactory is indicated, perhaps, by the many methods which have been proposed. Results of a comparative study of a number of these methods by Hucker and Conn²⁷ indicated that the methods of Jordan,²⁸ Buchanan,²⁹ Atkins,³⁰ and Hucker³¹ gave most satisfactory results. Hucker and Conn found the Gram stain to give variable results, even under the most carefully controlled conditions. In another publication Hucker and Conn³² reported results of a comparative study of the Gram stain in different laboratories. Slides were prepared bearing films of six different bacteria known to differ widely in their behavior to the Gram reaction. They were distributed to 10 different collaborators with identical directions. With four of the six organisms consistent results were secured. The other two organisms gave such variable results that it was impossible to consider them either Gram negative or Gram positive. Conn suggested that these organisms be called Gram variable.

Hucker's Modification of the Gram Stain. The following solutions are needed:

Solution A

Crystal violet (85 per cent dye content).....	4	grams
Ethyl alcohol (95 per cent).....	20	ml.

Solution B

Ammonium oxalate.....	0.8	gram
Water.....	80.0	ml.
Mix solutions A and B.		

Lugol's Iodine Solution

Iodine.....	1	gram
Potassium iodide.....	2	grams
Water.....	200	ml.

Counterstain

Safranin (saturated solution in 95 per cent alcohol).....	10	ml.
Water.....	100	ml.

Procedure. Stain for one minute with the crystal violet mixture; wash in water and then stain for one minute with the iodine solution; wash in water and dry with bibulous paper. Decolorize in 95 per cent alcohol for 30 seconds; counterstain for 10 seconds. Wash, dry, and examine.

The Ziehl-Nielsen Acid-Fast Staining Procedure. The original procedure of acid-fast staining is known as the Ziehl-Nielsen stain. There are many modifications of this procedure, the following being typical:

27. Hucker and Conn. 1923. N. Y. Agr. Exp. Sta. Tech. Bull. 93, 37.
28. Jordan. 1908. General Bacteriology, Saunders, Phila.
29. Buchanan. 1911. Veterinary Bacteriology. W. B. Saunders Co., Phila.
30. Atkins. 1920. J. Bact. 5, 321-324.
31. Hucker. 1921. J. Bact. 6, 395-397.
32. Hucker and Conn. 1927. N. Y. Agr. Exp. Sta. Tech. Bull. 128, 1-34.

1. Prepare film in the usual manner.
2. Flood with steaming carbol fuchsin for five minutes. The slide or cover glass may be immersed in the staining fluid and the fluid heated.

Basic fuchsin	1 part
Absolute alcohol	10 parts
Carbolic acid (1 to 20).....	100 parts

3. Wash in water.
4. Decolorize with 25 per cent hydrochloric acid. This will remove the red color.
5. Counterstain with methylene blue for about one minute.
6. Wash, dry, mount, if desired, and examine.
7. The film may be counterstained with picric acid if desired.

Negative Staining of Microorganisms. This technic which has become known as "negative staining" because the cells are unstained on an opaque black background was probably first described by Burri.³³ He diluted India or Chinese ink 1 to 10 with water and sterilized it in small portions of 5 to 10 ml. When used a drop of the diluted ink is inoculated with enough growth to give about one cell per droplet of .1 to 2 mm. in diameter. Then with the aid of a sterile pen or other instrument, groups of droplets of three are made on the surface of a solid medium. These droplets may be examined to determine the number of cells. Dorner³⁴ called attention to this method and outlined the technic as follows: Boil 10 gm. of nigrosin in 100 ml. of water for about 30 minutes. Filter several times through the same filter paper, adding 10 drops of formalin before the last filtration as a preservative. Place a small loopful of this solution on a clean slide and add the bacteria with a needle in loop. After mixing spread the mixture a little irregularly on the slide and dry either at room temperature or slowly over the flame. The preparation may be examined without use of a cover glass with the oil immersion lens.

Oxygen Relations. Relation of microorganisms to oxygen may be determined from the closed arm of fermentation tubes. Before using, however, it is advisable to reduce the dissolved oxygen to a minimum either by a vacuum pump or boiling.

Incubation of streak plates by means of Torrey's method will give good results. Also agar streaks of the organism may be incubated in a Novy jar.

Two methods are generally used by bacteriologists:

Agar Shake Method. The medium to be used, usually plain agar, is melted and cooled to about 45°C. (113°F.). The organism, the oxygen relations of which are to be studied, is inoculated into the melted agar, the agar thoroughly shaken and cooled. Strictly anaerobic bacteria will grow in the deeper layers of the culture but not at or near the surface.

Fermentation Tube Method. The appearance of growth in the closed arm of the fermentation tube is evidence of anaerobic growth.

Nutrient Broth or Bouillon. After this medium has been inoculated from a young culture of the organism, it should be incubated at its optimum temperature. The characteristics may be marked on the Descriptive Chart. These observations include pellicle formation, turbidity, etc. Be-

33. Burri. 1908. *Cent. Bakt.*, Pt. 2, 20, 95-96.

34. Dorner. 1930. *Stain Tech.* 5, 25-27.

sides these uses of the nutrient broth culture, it may also be used for observations for formation of hydrogen sulfide, indol, etc.

Pellicle formation is influenced by several different factors. Larson stated that surface tension was important. Bacteria which usually grow with pellicle formation were made to grow down in a medium whose surface tension had been depressed.

Welch's³⁵ Method of Cultivating and Examining Microorganisms. This method enables colonies of bacteria, yeasts, etc., to be cultivated on flat slips of glass covered with a very thin layer of solid culture medium, thus allowing subsequent examination of the colonies under a high magnification if necessary. Three slips of glass, about five inches in length, are placed in a test tube (seven by one inch) in the form of a triangle and after the addition of a small amount of an agar culture medium the tube is plugged with cotton wool and sterilized. The medium is melted by immersing the tube in boiling water and after cooling to about 50°C. (122°F.) the medium is inoculated and mixed by rotating the tube, after which this is tilted several times to allow the medium to run up and down the outer surfaces of the glass slips. It is then placed in cold water in a vertical position over the mouth of the tube to prevent evaporation during incubation. If necessary, the addition of five per cent of glycerol may be made to the medium as a further precaution against dessication. After growth is complete one or more of the slips may be removed with sterile forceps and a cover glass placed over the colonies of which microscopic examination is desired, the remainder of the slip being cleaned with damp cotton wool. The colonies of bacteria thus obtained are practically in one plane and may be stained or examined by dark-background illumination with facility.

Frost's³⁶ little plate method may also be used for studying the colonies of bacteria. The application of this technic to milk is given in Chapter 5. The technic is also outlined in the author's *Practical Bacteriology*.¹

Gelatin Liquefaction. Liquefying action on gelatin yields information on the proteolytic activities of an organism. Other proteins should also be used, since Diehl³⁷ has shown that bacterial proteases may be specific for certain proteins. The older method consisted of inoculating a tube of gelatin medium with a straight needle. The tubes were then held for six weeks to determine whether the medium was liquefied. Rothberg³⁸ proposed giving the organism a preliminary cultivation in one per cent gelatin solution at 25°C. (77°F.) or 37°C. (98.6°F.) and then inoculating the surface of gelatin medium in a culture tube incubated at 20°C. (68°F.) for 15 days. Rush and Palmer³⁹ reported that the results were influenced by the methods which were used. Levine and Carpenter⁴⁰ proposed the use of viscosity determinations. Liquefying bacteria caused a marked reduction in viscosity and a distinct increase in formol titration. The method was discussed further by Levine and Shaw.⁴¹ Allen⁴² also proposed a method based on changes in viscosity. The suggestions were founded on the procedure for measuring fluidity of starch. These methods have not had wide application. Before they are generally adopted, much more work would have to be done with them.

Frazier's⁴³ Method of Determining Gelatin Liquefaction. Plates are poured with gelatin-agar which contains .4 per cent of gelatin together with salts and small amounts of peptone and beef infusion. Duplicate plates are inoculated at the center to form a giant colony and incubated at 30°C. (86°F.) for 48 hours. Then one plate is flooded with an acid solution of bichloride of mercury while the other plate is flooded with a one per cent solution of tannic acid. In the first a clear zone around the giant colony indicates decomposition of the gelatin as far, at least, as peptones. Similarly a heavy precipitate about the giant colony in the plate flooded with tannic acid solution shows decomposition of the gelatin. There is also about the colony of an organism which breaks down gelatin to a considerable extent, a clear zone surrounded by a strikingly white halo. The tannic acid precipitates the gelatin and decomposition products down through some of the amino acids. By use of the two plates, then, a fair idea can be obtained of the amount of decomposition of the gelatin. Results were said to be available in two days.

Starch Hydrolysis. Methods for the determination of the action of bacteria on starch are about as unsatisfactory as those for studying gelatin decomposition. The starch agar plate described by Went,⁴⁴ Eijkmann⁴⁵ and Allen⁴⁶ seems to be as satisfactory as any method. Agar with .2 per cent of soluble starch may be used. After incubation, the medium is flooded with iodine solution. Eckford⁴⁷ used a soluble-starch broth. Other procedures were suggested by Gottheil,⁴⁸ Edson and Carpenter,⁴⁹ Crabill and Reed,⁵⁰ Smith,⁵¹ and Müller⁵² and others.

FERMENTATION REACTIONS

These are used by practically all microbiologists for identifying microorganisms and characterization of new species. The sugars to be used depend largely on the purpose of the investigation. Great care should be used in sterilizing carbohydrate media, since Mudge⁵³ and Hasseltine⁵⁴ have shown that polysaccharides are easily hydrolyzed to monosaccharides. The latter of these investigators found that serious errors were introduced in the study of *Bacillus proteus*, for instance, on common carbohydrates. For investigations requiring accurate data other methods of sterilization than moist heat should be used. The broth may be sterilized by filtration after the carbohydrates have been added, or the carbohydrate solutions may be sterilized by filtration and added to the broth with a sterile pipette just before the tubes are inoculated. For determining the reaction of media in fermentation tubes, it was once the custom to titrate five milliliters of the medium with N/20 NaOH (or HCl) with phenolphthalein as the indicator. Today the actual hydrogen-ion concentration is determined by any of several methods and with various apparatus. Reference may be

Determination of Acid Formation From Sugars. Acids without gas may be formed and consequently it is necessary to test the medium. Joffe and Conn⁵⁵ believed that many unwarranted statements have been made about acid formation from sugars. The presence of acid in cultures has been generally attributed to decomposition of sugars and the presence of alkaline compounds to peptone splitting. Working with certain soil bacteria, Joffe and Conn found that they imparted definite changes in media irrespective of glucose fermentation. The appearance of acid is influenced by several factors and should not be attributed entirely to sugar fermentation.

Carbohydrate Solid Media. Liquefiable solid media containing the carbohydrate may be used. The organism should be stabbed into the medium or incorporated in it, just before the medium hardens.

Conn and Hucker⁵⁶ have found agar slants to be more useful for determining fermentability of sugars than the old media. One per cent of the sugar is added to the agar the reaction of which is adjusted to pH between 6.8 and 7.2 by brom thymol blue. An indicator whose range lies just to the acid side of pH 7.0, such as china blue or brom cresol purple, is added. The following concentration of indicators was recommended:

Brom cresol purple.....	0.001 %
Brom cresol purple and cresol red, each.....	0.0005%
China blue	0.0025%
plus Na salt of rosolic acid.....	0.005 %

The data in some cases may be secured in a very short time. The method has much in common with Bronfenbrenner and Schlesinger's.

Paraffin Plugged Tubes. The carbohydrate medium may be overlaid with sterile paraffin. When gas is formed, the plug will be forced up away from the surface of the medium. This method was suggested by Beattie⁵⁷ when tests were to be made with rare sugars.

Ordinary Culture Tubes. The organisms may be inoculated into an ordinary culture tube without any special device. Gas formation may be determined by watching the tube for rising gas bubbles. They may be more readily observed by tapping the tube.

A method for analyzing the gases formed by bacteria in culture media, was described by Brown.⁵⁸

Bronfenbrenner and Schlesinger's⁵⁹ Method for Determining Fermentation of Carbohydrates by Microorganisms. Bronfenbrenner and Schlesinger, realizing the value of early fermentation results, suggested a method for securing results earlier than is possible by the ordinary procedure. They planted each of the suspected colonies (if doing confirmation work with *Escherichia coli*, or sample under study) in an agar drop. They outlined their technique as follows:

"One prepares a medium containing 1.5 per cent of agar, 0.5 per cent of sodium chloride, 1 per cent of peptone; this mixture is brought to boiling and the reaction not adjusted. At this point a suitable quantity of indicator⁶⁰ is added, the medium distributed into small tubes containing 1 or 2 cc. of medium in each, autoclaved for 20 minutes at 13 pounds pressure and stored on ice. When needed for use, this medium is melted and 0.1 or 0.2 cc. of 20 per cent lactose solution is added to each tube, thus

60. While litmus or any other indicator may be used, we find it especially convenient to use CR indicator, described in the September, 1918, issue of the Journal of Medical Research.

obtaining 2 per cent concentration of the carbohydrate. While hot this lactose agar is deposited in drops by means of a sterile capillary pipette on the inner surface of the bottom of a Petri plate. The drops can be placed very symmetrically and regularly if the outside of the Petri dish is previously marked to show the points at which the drops are to be deposited. Each drop is inoculated with the material from individual suspected colonies, leaving two drops on each plate inoculated to serve as controls of the original color of the medium. When all of the drops are inoculated, one places fresh drops of the same lactose agar over each one of the primary drops, thus securing conditions of slightly lowered oxygen tension, favorable for carbohydrate metabolism of bacteria. . . . Since CO_2 and some of the other acids produced by bacteria are volatile, the atmosphere of the Petri plate soon becomes saturated with these acids which may partly diffuse into the other drops and affect the color of the agar and so confuse the results. We found it possible to obviate this difficulty by inverting the plate and placing within its cover a circular piece of filter paper soaked in 2 per cent NaOH solution."

These authors regarded this method with favor. They also used a method wherein a sterile concave slide was used to hold the carbohydrate agar. After inoculation, a sterile cover glass was dropped over this.

Lindner's⁶¹ Method for Determining Fermentability of Sugars by Microorganisms. This method is especially applicable to rare expensive sugars which can only be used in small amounts. The fermentation vessel consists of a hollow microscope slide provided with a cover glass. The yeast, or organism, under examination is suspended in sterile yeast-water and a few drops are placed in the hollow of the slide; a small quantity of the sugar to be tested, previously powdered, is then added by means of a flattened platinum rod. The quantity of liquid used must be accurately gauged so as not to leave an air bubble and not to overflow the sides of the hollow when the cover glass is applied. Any slight excess of liquid may be removed by means of sterilized filter paper. The cover is made airtight by means of sterilized vaseline. The slide is kept in the incubator at 25°C . (77°F .) overnight and the relative fermentability of the sugar can be judged by the size of the bubble of carbon dioxide which has formed beneath the cover glass by morning. It is simplest and most convenient to perform the experiments in series; testing one organism against a series of different sugars, the slides of each series then afford a certain amount of control over each other. On account of the large excess of yeast, and the short duration of the test, it is not absolutely necessary to sterilize the sugars before use each time. A bubble of carbon dioxide may be distinguished from a bubble of air by placing a drop of caustic alkali on the edge of the cover glass.

Schmidt-Jensen's⁶² Method for Determining Fermentation of Carbohydrates by Microorganisms. Schmidt-Jensen worked out a micro method for use with the rarer substances and showed that with inverted tubes it was satisfactory with quantities of half a milligram of the carbohydrate, thus giving 2,000 possible estimations per gram—a quantity 40 times less than that required in the ordinary way. Glass tubing 1.5 mm. in diameter was used, and one end was slightly constricted in the flame. The other end was provided with a cotton plug armed with an insect needle for convenience of handling, or plugged in the ordinary way. The tubes were about 100 mm. long. After dry sterilization, a quantity of broth was sucked in. This was easily controlled by measuring the length of the column of the fluid, 56.5 mm. corresponding to .1 ml. in a 1.5 mm. tube. After the end of the tube was removed from the broth it was sealed, care being taken not to burn the contents, which can be dislodged to the closed end by tapping gently on a table. It was stated that all air bubbles should be made to burst before the tubes are sterilized, during which process they should be protected from moisture by cotton-wool or filter paper. Inoculations were made with a fine wire or with capillary tubes, the tubes being closed by the plugs above mentioned or by means of an outside cotton-wool closure. This is applied by taking a series of tubes (four cm. long and five mm. dia.) containing very loosely-packed cotton wool into which the microculture is *inverted*.

61. Lindner. 1900. Woch. f. Brau. 336.

62. Schmidt-Jensen. 1920. Meddeler f. d. Kgl. Vet. oz. Land.

Schmidt-Jensen also discussed the value of bacterial fermentation tests as a control of chemical purity of carbohydrate preparations. They were able to detect the presence of foreign sugars in those which were thought to be pure.

Stiles and Peterson's⁶³ Method for Rapid Determination of Sugar in Bacterial Cultures. Stiles and Peterson stated that it was preferable to analyze the culture for its unfermented sugar instead of determining titratable acid, hydrogen ion concentration, or using other indirect means of measuring sugar fermentation. This can be done quickly and accurately by means of the Shaffer-Hartmann micro-method as adapted to bacterial cultures. They described the following technic:

Ten ml. of culture should be placed in a 50-ml. volumetric flask, neutralized with NaOH, clarified with one ml. of lead subacetate (30%) and without removing the precipitate delead with three ml. of disodium phosphate (10%) and the volume made to 50 ml. The contents are shaken by inverting; in about three minutes the precipitate has settled and two ml. may be removed without filtration for determination of sugar by the micro-method of Shaffer and Hartmann. The procedure is accurate to within 10-20 mg. per gm. of sugar. If a somewhat less degree of accuracy is sufficient, as is usually the case in determining the question of the fermentability of the sugar, one ml. of culture should be removed with a sterile pipette, neutralized, made to five ml. and the sugar determined without clarification. This modification gives results that are one to two per cent higher than when the culture is clarified.

Hasting's⁶⁴ Method for Determining Casein Hydrolysis. Melt and cool some plain agar at 50°C. (122°F.), add 10 per cent of sterile skimmed milk, and pour into sterile Petri dishes. Allow the medium to harden. Streak the culture across the surface of the medium and incubate. Proteolytic action will be indicated by a clear zone immediately about the growth. To make certain that this clear zone is due to proteolysis, flood the plate with dilute acetic acid; if the clear zone remains, it will indicate that it is due to proteolysis.

Conn's⁶⁵ Method for Determining Production of Rennin by Bacteria. Conn proposed the following method for determining the production of rennin. Inoculate the pure culture into milk in the usual manner. Incubate for a time sufficient to allow the organism to produce distinct change in the milk with the formation of at least .5 ml. of whey on the surface. At the end of this incubation period secure some fresh, unsterilized milk. Place 10 ml. in a test tube and add .5 ml. of the whey from the milk culture and place in the 37°C. (98.6°F.) incubator. Examine every five minutes for the first half hour and if not curdled then, at less frequent intervals for a few hours longer. With active rennin-producing organisms, the milk will be curdled in a half hour.

Formation of Hydrogen Sulfide. Variable results may be secured in this test, depending on the peptone which is used. Some commercial peptones contain sufficient cystine, as discussed in the chapter on "Media" to give a test for hydrogen sulfide. Others may not, even though the organism is able to produce it. Various procedures have been devised for detecting its formation.

Bibulous Paper Method for Determining Hydrogen Sulfide Formation. A strip of bibulous paper impregnated with lead acetate may be suspended above the plain broth culture. This will be blackened by hydrogen sulfide which rises from the medium. Precautions must be used to maintain sterility and control tubes should be used.

Lead Acetate Agar Method for Determining Hydrogen Sulfide Formation. This method was used by Kligler.⁶⁶ The composition of his medium is given in Chapter 26. The lead acetate agar may be slanted or not in the culture tube. The medium will be darkened or blackened along the line of inoculation. Wilson⁶⁷ used a ferric chloride

medium in which the iron acted as the indicator of sulfide formation. If desired, any of the media described here may be used in Petri dishes. They may be melted and poured into the dishes and allowed to harden, after which the organisms may be streaked on the surface or the agar may be inoculated and poured into the dish. If the lead acetate agar slant is used, it should be inoculated both on the surface as well as in the butt.

Experiments by Hunter and Crecelius⁶⁸ to determine the sensitivity of ferric ammonium citrate and bismuth liquor for detecting hydrogen sulfide definitely showed the superiority of bismuth over iron irrespective of the pH. The most sensitive range of iron was in alkaline menstruum while with bismuth the pH had no effect. The variable factor was the tryptone, not all lots being uniform composition. The bismuth sulfite medium was reported to be superior to any containing lead or iron. Hunter and Crecelius stated that in reporting results of tests on hydrogen sulfide formation, the method used be stated.

FAT DECOMPOSITION

This is an important subject in the food industry. Microorganisms which decompose fats are of interest mainly because of the products which they form. These impart bad odors and flavors to the fats. Two fine reports have been published on this subject by Lea⁶⁹ and Jensen and Grettie.⁷⁰ The latter covers the microbiology of fat decomposition very satisfactorily.

Early work by Schreiber⁷¹ showed that pure fat is not decomposed by bacteria. Nutrient materials and oxygen were said to be necessary. Cleavage was most rapid when the fat was finely divided as in an emulsion. Experiment by Söhngen⁷² and Kraay and Wolff⁷³ showed the lipolytic abilities of microorganisms to be more common than had been believed. The latter workers showed that lipolytic action of bacteria was somewhat specific. Some split both lecithin and fat while other species split only one. More information of this nature resulted from Seliber's⁷⁴ experiments. Such oils as cod-liver and olive oils are utilizable by bacteria. Heukelekian⁷⁵ observed that the carbon in these fats could serve bacteria. These oils are typical oils serving as foods and are therefore subject to microbial decomposition. Large amounts were said by Tuason and Shapiro⁷⁶ to be oxidized by bacteria in spite of the relative slowness of the process; they observed that 45 per cent of the raw oil introduced into a culture may be oxidized.

Forty pure cultures of bacteria were allowed to act on triolein in experiments by Castell and Garrard.⁷⁷ Most of the Gram-negative lipolytic bacteria also oxidized the fat; there appeared to be a definite relation

between the "oxidase reaction" of a bacterial colony and the ability of the organism to produce oxidative rancidity. Lipolytic activity, as indicated by the color reactions of Nile-blue sulfate and methylene blue and blue soap formation with copper sulfate, was shown to coincide with that of the same organism as measured by titratable acidity they produced in larger samples of the oil. Castell and Bryant had shown earlier that color changes in Nile blue sulfate and similar media must be interpreted carefully.

While it is known that fats are susceptible to decomposition by many microorganisms, the above discussion holds mainly when they are added to culture media. They apparently function in about the same manner in natural foods and may be responsible for some of the undesirable changes which are observed. Vickery⁷⁸ observed lipolysis of beef fat by one strain of *Achromobacter* and several of *Pseudomonas* and asporogenous yeasts. Vickery did not believe, however, that the level of free acidity of beef fat could be used as an index of spoilage occurring in beef fatty tissues. These organisms were capable of growth at low temperatures. Lipolytic activity was said to be distributed in a random fashion among strains of each genus. Hammer and Collins⁷⁹ reported lipolytic bacteria to be common in dairy products. They were present in butter which had become rancid and which had been churned from raw cream. Lipolytic bacteria were relatively scarce in fresh butter made from pasteurized cream. This work seemed to show that one type of rancidity in dairy products was caused by lipolytic bacteria.

Several methods have been devised for detecting and estimating the number of lipolytic bacteria in foods. Among the first media for this purpose was Nile-blue sulfate agar in which the fat was dispersed. Butter fat was commonly used in this medium by Hammer and Collins. This medium employs the contrasting pink of unchanged fat and blue of hydrolyzed fat. The differentiation was said to be easy by Long and Hammer,⁸⁰ but the toxicity of the dye and the necessary flooding disturbs colonies. They substituted acid-base indicators and copper sulfate for Nile-blue. Demeter⁸¹ reviewed the merits and difficulties encountered in using the more important methods, such as Eijkmann's natural fat, Barry's copper salts, Anderson's tributyrin, and Turner's Nile-blue with Stark and Scheib's modification. Since Nile-blue is markedly toxic to many microorganisms and often indicates spurious lipolysis, owing to production of acid from sources other than fat, Demeter suggested extracts previously fermented by coliform bacteria to remove all traces of carbohydrates, and which might be rich in nitrogenous substances and vitamins. To overcome toxicity of Nile-blue, China blue was suggested as a substitute; the latter allowed some of the fungi to develop which did not develop on Nile-blue but gave less sharp differentiation.

Turner's⁸² Method for Fat Decomposition by Bacteria. Turner devised a medium which could be used for following bacterial lipolysis in the intestines. Its formula is given in the chapter on "Media." The lipase-producing colony is characterized by a dark blue zone surrounding it in striking contrast to the dull bluish-gray color of the remainder of the plate. The colony, itself, is usually colorless. The zones are usually greater in diameter than the colonies except in those with a marked tendency to spread. When examined under the low power of the microscope, the zone is seen to be made up of tiny blue globules or shapeless masses of the same color. None of the colorless globules of oil seen elsewhere through the plate is observed in the zone. If the colony under study is well separated from others, a faded circular zone two to three mm. wide is observed surrounding the blue zone.

In some cases colonies themselves may take the color. In such cases, it is necessary to distinguish between a blue colony and a blue zone which is usually not difficult. Jensen and Grettie⁷⁰ modified Turner's medium. Their modification is given in the chapter on "Media."

Opaqueness in the fat globules surrounding lipolytic colonies in fat-emulsion agar plates is owing, at least in part, according to Castell and Garrard,⁸³ to rapid formation of fat crystals as well as to formation of fatty acids. The rapidity with which crystals form and their general conformation and texture are capable of considerable variation. This depends on the previous history of the fat, temperature, and the characteristics of the agar medium in which the fat is suspended.

Ammonia Production. Demonstration of formation of ammonia in cultures of bacteria is an unsatisfactory procedure. Formerly it was customary to use Nessler's reagent. The culture was diluted with ammonia-free water and a little Nessler's reagent was added. Presence of a yellowish-green color indicated the presence of ammonia. This method was given up because many uninoculated media gave strong tests for ammonia. The advantages of being able to use a solid medium for determining ammonia caused Hucker and Wall⁸⁴ to develop such a method. They prepared a solid medium, the formula for which is given in the chapter on "Media." As a test of ammonia production from organic compounds, one ml. of a 10-per cent phenol and one per cent (available chlorine) sodium hypochlorite solutions are added to the surface of an agar slant after incubation at the optimum temperature. A blue color appears in one-half hour if ammonia is formed.

Hansen's⁸⁵ Method for Detecting Ammonia Production by Bacteria in Agar Slants. The difficulties encountered in maintaining hypochlorite solutions for the Thomas test for ammonia prompted Hansen* to seek a new reagent. He found that hypobromite solution gave just as good results. The reagent was prepared by adding 25 ml. of 2N sodium hydroxide to 100 ml. of saturated bromine water. The bromine water may be made by adding a sufficient amount of bromine to cold, distilled water in a glass-stoppered bottle. Hansen stated that such solutions are quite uniform—at least suffi-

* Hansen's reagents have the following composition:

I.		II.	
Thymol	2 gm.	Bromine water	100 ml.
Sodium hydroxide	10 ml.	Sodium hydroxide	35 ml.
Water	90 ml.		

ciently so for the test. Thymol was used by Hansen in place of phenol as required in the Thomas test.

The test is carried out by adding one ml. of the thymol solution and hypobromite successively to the culture and allowing it to act for 20 minutes. If ammonia is present, the mixture becomes blue or greenish blue.

Nitrate Reduction in Nitrate Broth. The amount of nitrate decomposed readily by an organism may be determined quantitatively by the aluminum-reduction method which is commonly used in water analysis. For qualitative results the presence of nitrites or ammonia in a medium free from these substances before inoculation may be taken as sufficient evidence of nitrate reduction.

The presence of a reductase for nitrates was regarded as an important characteristic by the early workers. The method for conducting the test was considered quite simple. Conn and Breed,⁸⁶ however, carried out a thorough investigation which would indicate that the test is not as simple as commonly thought. They pointed out certain sources of error which might be mentioned here: (1) Poor growth; (2) presence of more readily available nitrogen; (3) reduction without accumulation of nitrite. These authors claim that an organism must not be called a non-reducer until exhaustive studies have been made.

The Griess method has been generally used for detecting the presence of nitrite in water, cultures, meat-curing solutions, etc. It is based on the formation of azobenzolnaphthylamin whenever naphthylamin and sulphanilic acid are present in an acid solution of nitrites. It is a delicate test and is considered by some to be too much so for bacteriological work. A control tube should always be made to check the dilution water, etc.

Wallace and Neave⁸⁷ stated that fading in the standard nitrite test was caused by an excess of nitrite. The substitution of dimethyl-alpha-naphthylamine for the alpha-compound was reported to give a reagent of high sensitivity and to produce a permanent nitrite color.

As stated above, we are indebted to the investigations of Conn and Breed for better methods for determining nitrate reduction. The test may be run in both liquid and solid media.

Nitrate-Peptone-Agar. Prepare this medium according to the formula in Chapter 26 and slant in culture tubes. Inoculate by streaking the surface in the usual manner and incubate. Test for the presence of nitrite by placing a few drops of the reagent-dimethyl-alpha-naphthylamine on the surface of the slant. The appearance of a red or pink color indicates the presence of nitrite. Always run a sterile control tube.

Nitrate-Peptone-Broth-Method. The nitrate-peptone broth should be sterilized in culture tubes, inoculated with the organism and incubated. At the end of the incubation period, add a few drops of the indicator. Always run a sterile control tube.

Synthetic-Nitrate-Medium Method. The formula for this medium is given in Chapter 26.

Randall and Reedy⁸⁸ suggested a simple method for determining bacterial reduction of nitrate. A solution of potassium nitrate is added to a suspension of bacteria cells and, after 15 minutes to one hour, the mixture

is tested for nitrite. This procedure was used on 24 different species of bacteria and gave complete agreement with the routine method which consisted in inoculating broth containing potassium nitrate with the test culture and testing for the presence of nitrite after incubation.

Pathogenicity to Animals. It is frequently necessary to determine whether bacteria which have been isolated from foods are detrimental to human beings. Bacteriologists, in this case, have to resort to the use of experimental animals. However, data secured with animals must be carefully interpreted. There is possibility for error in applying results secured with animals to human beings. An organism, or its toxin, which is detrimental to animals, might have no such action on human beings. Furthermore, selection of animals which shall be used, is frequently determined by cost as well as by convenience. Guinea pigs, rabbits, mice, chickens, and kittens have been used in many investigations in the field of food bacteriology. Those who wish to study the methods of handling animals should consult the discussion of the subject by Kolmer and Boerner⁸⁹ as well as Leaflet VII, The Study of Pathogenic Aerobes, May, 1940, Manual of Methods.

Oral Administration. This method of using animals is perhaps the most useful to the food bacteriologist. Oral administration is the most direct method of studying the toxins of *Clostridium botulinum*. Before conclusions are reached on the poisonous properties of any substance which may be present in foods, it should be fed by mouth. Many data supposed to support the poisonous properties of "ptomaines" were secured by injection experiments and not by feeding. In fact, very few of the compounds which would be classed with ptomaines have been studied by feeding. Conclusions as to their poisonous properties are based almost entirely upon injection experiments.

In a study of the possible toxic effects of putrified foods, Savage used kittens stating that they were more sensitive than other animals to such foods. Guinea pigs have been used in the laboratory for feeding experiments with *Clostridium botulinum*.

Müller⁹⁰ claimed that animal feeding should supplement chemical and bacteriological examination of meat. He claimed that the presence or absence of certain poisons in food cannot be determined otherwise than by feeding. Schellhorn⁹¹ reported that not much reliance can be placed on the mouse-feeding method for determining the fitness of meat for consumption. Mice were fed normal meat and many of them died.

Intraperitoneal Injections. These must be made with great care in order not to puncture the intestines. Intraperitoneal injections into such small animals as mice are not easily made. Peritonitis may result if the intestines are entered or the organism which is injected may not produce its effects.

91. Schellhorn. 1910. Centbl. Bakt. 54, 428-450.

Intravenous Injection. There are injections directly into the circulatory system. They require usually the larger animals. Rabbits are usually injected in the posterior auricular vein in the ear. Roth⁹² suggested a convenient method for injecting guinea pigs intravenously.

Subcutaneous Injection. Such injections are made by introducing the substance under study under the skin.

THERMAL DEATH TIME

Data from such determinations must, obviously, be collected under very carefully controlled conditions, else they may not be compared with those secured by others. The Society of American Bacteriologists once recommended that the organism be exposed in nutrient broth for 10 minutes when this medium is adapted to the growing of the organism. Sternberg in the early days proposed sealing the organisms in a tube before exposure to the heat. The Sternberg bulb consisted of a glass bulb with the neck tapering down to a fine bore, the neck being at right angles to the bulb. To fill it, the bulb was gently heated, after which the tip was immersed into the culture of which the thermal death time was to be determined. As the bulb cooled, some of the culture was drawn into it. The neck was then sealed in the flame. The bulbs were suspended by a wire in a water or oil bath, the temperature of which was raised periodically. Eijkmann⁹³ pointed out that such treatment might so devitalize the cells that they would be slow to reproduce. Brown and Peiser⁹⁴ and others have used other methods.

Results of thermal death-time determinations are influenced by many factors some of which have been discussed in the chapter on "Canning." Magoon⁹⁵ and many others have pointed out that heat resistance of spores is not a fixed property but subject to many variables. Dickson *et al.*⁹⁶ observed marked variations in heat resistance of spores of *Clostridium botulinum*. Consideration of results on this subject found in many publications tempts one to wonder just how far thermal death-time results should be accepted. They probably hold only for the exact conditions under which they were determined. The most difficult controlled element and one impossible of exact duplication is the spore itself. Variations in thermal death-time which have been attributed to certain factors, such as salt, may have been due to variable resistance of the spores in the suspension.

The following are said to affect the heat resistance of bacterial spore suspensions:

1. *Nutritional Status of the Organism.* Spores produced in various media have been shown to possess quite different resistances to heat. Williams⁹⁷ produced spores of *Bacillus subtilis* under a wide variety of nutritive and environmental conditions and exposed them to high temperatures. The strain which he used gave a basic resistance

95. Magoon. 1926. J. Bact. 11, 253-283.

96. Dickson *et al.* 1922. J. Amer. Med. Assoc. 79, 1239.

97. Williams. 1929. J. Infect. Diseases 44, 421-465.

of six minutes at 105°C.(221°F.), 14 minutes at 100°C.(212°F.), and 35 minutes at 95°C.(203°F.). By changing the nutritive substrate, the heat resistance of the spores was changed. The type but not the concentration of peptone used in the medium was important. Spores of greater heat resistance were secured from casein digest medium. The higher the incubation temperature, the greater was the resistance to heat. Other factors were also mentioned as causes of changes in heat resistance. Another investigation which brought out the effect of the medium was that by Sommer⁹⁸ with spores of *Clostridium botulinum*. The details of this work need not be presented here but they show that the nutritive condition of the organism is very important. Spores of *Clostridium botulinum* grown in four per cent peptone showed resistance of one and one-half to two and one-half hours. Addition of phosphate raised the heat resistance to four hours.

Curran and Evans⁹⁹ observed that spores which had been exposed to ultraviolet light were sensitive to heat. Ultraviolet rays of wave lengths longer than 2000 Å under suitable conditions sensitize spores to heat. Angerer¹⁰⁰ also reported evidence that various treatment of spores altered their heat resistance. Defatting bacterial spores, for instance, decreased their resistance. Other agents either decreased or increased heat resistance. One cannot help but wonder whether they were due to the agents and conditions imposed on the spores or to unavoidable variations in the experiments.

2. *The Particular Strain Studied.* No two strains of bacteria are just alike. Results collected with just one strain do not necessarily represent others. This was noticed by Dickson *et al.*⁹⁶ who studied the resistance of 40 strains at 100°C.(212°F.). These varied in resistance from 30 minutes to six hours. A very heat resistance strain was studied by Esty and Meyer.¹⁰⁴ They reported the following heat resistances for its spores under artificial but favorable conditions when heated in phosphate solution at pH 7.0.

- 4 minutes at 120°C.(248°F.)
- 10 minutes at 115°C.(239°F.)
- 32 minutes at 110°C.(230°F.)
- 100 minutes at 105°C.(221°F.)
- 330 minutes at 100°C.(212°F.)

While these resistances of *Clostridium botulinum* to heat are widely quoted and used in calculations for canned food processes the author is not aware that they have been secured by other investigators since. Especially is this true for the resistance of 330 minutes at 100°C.(212°F.). The strain and spore suspension used by Esty and Meyer was undoubtedly much more resistant to heat than strains now used in experimental work.

3. *Reaction of the Menstruum in Which Spores Are Heated.* This is an important factor in the food-preservation industry. Microorganisms are much more easily killed by heat in an acid than in an alkaline solution. Weiss¹⁰¹ observed lowered heat resistance with spores of *Clostridium botulinum* in the presence of acid ions. The greatest resistance to killing by heat occurred close to the neutral point; as the hydrogen-ion concentration increased a rapid reduction in that resistance resulted. This was emphasized in a practical manner in Weiss'¹⁰¹ second paper in which the effect of pH of foods on heat resistance of spores of the above organism, was shown. In acid foods, such as egg plums, the spores survived only about 10 minutes, whereas in foods pH of which was on the alkaline side of the neutral point, about 170 minutes were required (lima beans, pH 5.7).

Murray¹⁰² found that the greatest heat resistance of spores of *Bacillus anthracis* was shown in all cases at pH 8. While much of the work on this subject has been done with microorganisms in food products, results with other materials are confirmatory. Increase in acidity made it easier for Sabalitschka and Maas¹⁰³ to sterilize soil. The

subject was studied by Weiss¹⁰¹ from the standpoint of various canned foods. The hydrogen-ion concentration of the food was observed to be very important. *Clostridium botulinum* in more acid foods was destroyed much more easily than in alkaline. According to Dickson *et al.*⁹⁸ spores propagated in a neutral medium showed greater heat resistance than those from acid or alkaline media.

4. *Concentration of Organisms or Spores.* This is another important factor. It is reasonable that it would require more drastic treatment, either more heat, a longer time, or both, to destroy many cells than a few. This is important in food preservation, for it is the basis for efforts to keep bacterial loads of foods to be processed by heat, low.

About everyone who has worked on heat resistance has found this to be the case. Weiss¹⁰¹ observed it with *Clostridium botulinum*. Convincing evidence on this point was published by Esty and Meyer¹⁰⁴ from experiments with *Clostridium botulinum*.

5. *Age of Spores.* This has been found by many to influence heat resistance of suspensions. Weiss¹⁰¹ found that young moist spores of *Clostridium botulinum* had a greater heat resistance than old moist spores. Spores one month old were found to be three times as resistant as spores five months old. A general decrease in resistance was believed to occur as the spores age. The more resistant individuals changed more rapidly than the less resistant. Esty and Meyer¹⁰⁴ stated that young moist spores, probably those of the first generation, were most heat resistant. They worked with spores of *Clostridium botulinum*. Magoon¹⁰⁵ used an aerobic spore forming organism *Bacillus mycoides*. The heat resistance became greater for about 30 days, was constant for a second 30-day period and then gradually fell off. There was some fluctuation in resistance which might have been due to technic.

Dickson and his colleagues⁹⁸ also noticed considerable variation in heat resistance among spores of the same culture of the same strain. About 95 per cent of the spores were destroyed in relatively short time but among the remaining five per cent were some highly resistant spores. Spores from old cultures were observed to be more resistant than from young cultures.

Heat resistance of non-spore-forming bacteria is also influenced by age of the cells. Robertson¹⁰⁶ observed that young, rapidly growing, or adolescent, cells are more susceptible than older, mature cells to destruction by high temperatures. He used three heat-resistant species, *Microbacterium lacticum*, *Sarcina lutea*, and *Streptococcus thermophilus*. Stark and Stark¹⁰⁷ also found that young cells of *Streptococcus fecalis* and two species of encapsulated bacteria were markedly less resistant to heat.

6. *Presence of Salt.* This would be expected to affect heat resistance. The subject is of interest because several foods are salted before they are heated to preserve them. The results of observations on it, however, are not always in agreement. This may be due to the fact that different species were used as well as to conditions which obtained in the experiments. Weiss,¹⁰¹ working with *Clostridium botulinum*, stated that presence of salt materially lowered the heat resistance, the rate of lowering being proportional to the amount of salt. Viljoen,¹⁰⁸ on the other hand, observed that salt up to four per cent concentration protected spores of canned food spoilage bacteria in pea liquor.

7. *Influence of Sugar.* Microorganisms are more difficultly destroyed by heat in sirups or in the presence of sugar. This seems to be the case with practically all of the bacteria which have been used. Weiss¹⁰¹ observed it with spores of *Clostridium botulinum*. The heavier the sirup, the longer was the time required to kill the spores. About the same conclusions were reached by Fay¹⁰⁹ in studies on pasteurization of ice cream mix. Addition of sugar made it more difficult to destroy microorganisms.

These observations are based on alterations in the environment of the cells which make it harder to destroy the cells rather than to make any change in the cell itself. Slower heating of heavy sirups may be the best explanation.

Baumgartner and Wallace¹¹⁰ also observed a protective effect of sugars when microorganisms are heated. Concentrations of sucrose up to 50 per cent had no effect on heat resistance of spores in either acid or alkaline solutions. These investigators attributed this to a resistant spore envelope. With nonsporulating organisms, such as *Escherichia coli*, a minimum concentration of 10 per cent of sucrose protected the cells.

This phenomenon is apparently not restricted to bacteria, for Rahn¹¹¹ and Peterson and Levine¹¹² observed it with yeasts. Baumgartner and Wallace, however, did not observe it with strains of *Torula* heated in varying sugar concentrations in neutral media.

The practical significance of this matter was shown by Braun¹¹³ in studies on "dry sweetening" of nonacid canned foods. In contrast with the conventional method of adding sugar in the form of a syrup, some canners have attempted to add dry sugar to the empty container before the food product was added. The assumption was that the sugar would dissolve and distribute itself throughout the can. When spoilage occurred, it was found that the sugar had layered in the can and caused an average decrease of 32 per cent in the thermal effect of the sterilizing process of 70 minutes at 116°C.(240°F.). This decrease in sterilizing efficiency was caused by the fact that at one place in the can there was a heavy syrup where the sugar had not completely dissolved.

8. *Influence of Fat on Heat Resistance.* While too little information is available to permit general conclusions, it is generally believed that microorganisms in fat are protected from the action of heat. This, if it is true, may be due to actual inhibition of penetration of heat through the fat, or to the absence of moisture. This position was defended by Rogacheva¹¹⁴ who worked with common aerobic sporeforming bacteria of the subtilis-mesentericus type. He believed that the anhydrous condition of fats and oils explained survival of microorganisms in them when subjected to heat. Spores survived only when the fats were free from moisture.

Dried Spores. Water has generally been considered necessary for destruction of bacteria. This has been borne out in the food industry in the few investigations which have been completed on the subject. Cameron, Yesair, and Williams¹¹⁵ observed destruction of streptococci in 305 minutes at 55°C.(131°F.) in the moist condition, but an exposure of 230 minutes at 110°C.(230°F.) was required when they were heated in the dry state. Similar results were secured with putrefactive anaerobes and thermophilic bacteria. Spores were also found to be more resistant in oil free from moisture than in the same oil with moisture. Similar results were observed in general by Murray¹⁰² with *Bacillus anthracis*, *Clostridium tetani*, and *Clostridium welchii*. Absence of moisture made it necessary to heat the spores at higher temperatures for destruction. These data may be important in those food-preservation industries in which fats or oils are heated for preservation. In experiments of Sommer⁹⁸ with spores of *Clostridium botulinum*, drying on sand had little effect on their resistance to heat. Esty and Meyer¹⁰⁴ also observed no change in heat resistance of the same spores during storage in the dry state.

Oag¹¹⁶ found that spores of various virulent strains of *Bacillus anthracis*, *Bacillus welchii*, *Vibrio septique*, and *Bacterium anthracoides*

require an exposure to 400°C.(752°F.) (dry heat) for 20 to 30 seconds before they are killed. At lower temperatures, longer exposures are necessary. By constructing a graph it seems probable that these spores may withstand even higher temperatures for a few seconds.

Two and one-half hours' heating were required in a hot-air oven for destruction of *Bacillus subtilis* (Barkworth¹¹⁷). Within 30 minutes a temperature of 160°C.(320°F.) was reached in the interior of vessels being sterilized, while 200°C.(392°F.) was recorded on a thermometer in the oven.

Heat Resistance of Nonsporeforming Bacteria. Nonsporeforming bacteria are generally considered to possess little resistance to heat. Much of the work on these bacteria is open to criticism because of the fact that quantitative data were not collected and the heating times were not properly spaced. More recently it has been found that more knowledge of the heat resistance of nonsporeforming microorganisms is necessary in preservation industries which involve acid foods. Baker and McClung¹¹⁸ pointed out some of the points of technic which should be observed. Their work was done with *Escherichia coli*. Its thermal death-time at 57.3°C. (135°F.) was between 20 and 30 minutes. Working with an initial concentration of five to 10 million cells in broth at pH 7.05 Beamer and Tanner¹¹⁹ found the following times in minutes necessary to sterilize the suspension:

	55°C.(131°F.)	65°C.(149°F.)	60°C.(140°F.)
<i>Eberthella typhosa</i>	23.8 min.	8.9 min.	4.3 min.
<i>Salmonella paratyphi</i>	8.9 min.	4.3 min.
<i>Salmonella schottmülleri</i>	18.8 min.	13.8 min.
<i>Salmonella typhi-murium</i> ..	23.8 min.	13.8 min.
<i>Salmonella enteritidis</i>	23.8 min.	13.8 min.
<i>Staphylococcus aureus</i>	18.8 min.

In the brewing industry nonsporeforming microorganisms must be killed by heat. Epstein and Snell¹²⁰ who worked with both yeasts and bacteria reported that the heat resistance of *Lactobacillus pedicoccus* (*sarcinae*) and *Acetobacter* decreases, all being killed in 10 minutes at 60°C.(140°F.). Of the yeasts examined, the same order of heat resistance was observed for *Saccharomyces pastorianus*, *S. ellipsiodeus*, and brewers' culture yeasts, *Mycoderma* and *Torula*. Excepting the first two all were killed within five minutes at 54°C.(129.2°F.) and within 10 minutes at 52°C.(125.6°F.). The two first named yeasts required five minutes at 66°C. (150.8°F.) for destruction. Yeast spores were killed within 20 minutes at 58°C.(136.4°F.) and within 15 minutes at 60°C.(140°F.).

METHODS FOR THERMAL DEATH-TIME DETERMINATION

Most of these methods have been developed in the canned food field because it is so necessary to know heat resistance of various microorgan-

isms. Recently, greater efforts have been made to heat the organisms in the food itself or in an extract. Even the latter along with phosphate solutions, presents conditions quite different from those which exist in the food itself. Ball¹²¹ classified heat-resistance test methods as follows:

"(1) Heating microorganisms in a highly buffered, nonnutrient, aqueous solution and then *subculturing* in a nutrient medium to determine whether or not any microorganisms remained viable through the heating treatment;

"(2) Heating microorganisms in a highly buffered, nonnutrient, aqueous solution and then *plating* in a mixture of agar and broth to permit counting of the viable organisms remaining after the heating treatment;

"(3) Heating microorganisms in the food under investigation, and then incubating *without transferring* the microorganisms from this material, so that growth of the organisms that remained viable through the heating treatment will occur.

"(4) Heating microorganisms in the food under investigation, and then *plating* in a mixture of agar and broth to permit counting the viable organisms remaining after the heating treatment."

Bigelow and Esty's¹²² Method for Determining Thermal Death Time. Thermal death point in relation to time was defined as the time necessary to destroy a known number of spores at each of several temperatures. The organisms studied are isolated from the foods (usually canned foods spoiled on account of understerilization). The temperatures used are from 100°C.(212°F.) to 125°C.(257°F.) at intervals of five degrees. The medium used is the juice expressed from canned peas, corn, spinach, pumpkin, string beans, lima beans, baked beans, beets, or milk. A De Khotinsky electric bath with a thermo-regulator attachment is used, containing Crisco instead of water; the temperature is kept uniform throughout the bath by means of a turbine stirrer. A steam-heated bank of cells¹²³ may also be used in laboratories where such apparatus is available.

Cultures of the organism to be tested are grown on nutrient agar slants until a luxuriant growth occurs along the inoculated area (about 48 hours). This growth is then inoculated into nutrient broth of pH 7.0 and incubated at the optimum temperature of that specific organism for one week. One ml. of this suspension is inoculated into 10 ml. of the medium to be used and heated to 85°C.(185°F.) for 15 minutes to kill all vegetative forms. Special culture tubes, 7 mm. (inside diam.) x 250 mm. long (or 125 mm. if desired) and 1 mm. thickness of wall, are sterilized and inoculated with a suspension of spores of the organism under study.

The tubes are sealed off to within two inches of the surface of the liquid, placed in a Wasserman rack, and held temporarily in an ice bath until heated. The rack of sealed tubes is transferred to the oil bath, adjusted to the desired temperature, and subjected to this temperature for different lengths of time. Upon removal from the bath the tubes are cooled in ice water and held in an ice box until determinations can be made on the sterility of these cultures after heating. The initial count should be made according to Standard Methods, and the hydrogen-ion concentration of the medium should be determined.

This method usually shows the presence of "skips" when a single series of tubes is run. Esty suggests that large number of tubes, at least 25, be heated at four different times.

Hastings, Fred, and Carroll¹²⁴ believed that the "skips and stops" recorded by different investigators in thermal death-time work were due to imperfections in technic, such as uneven suspensions of cells, contamination, or the selection of an unsuitable

121. Ball. 1942. Ind. and Eng. Chem. 35, 71-84.

122. Bigelow and Esty. 1920. J. Infect. Diseases 27, 602-617.

123. This is a series of six or eight steam-heated brass cylinders about 10 inches high and eight inches in diameter. They may be tightly closed. The sealed thermal death-time tubes are placed in them and heated under pressure. This permits heating a considerable number of tubes in a shorter time.

124. Hastings, Fred, and Carroll. 1926. Centbl. Bakt. II, 67, 162-166.

medium into which the heated cells are placed. They believed that these inconsistencies could be overcome by a general improvement in technic. Williams¹²⁵ also used a modification of this technic when studying the resistance of the spores of *Bacillus subtilis* to heat.

Esty and Williams¹²⁶ Method for Determining Heat Resistance of Bacterial Spores. Esty and Williams encountered "skips" in thermal death-time work and reported a modification of the Bigelow and Esty technic designed to avoid them. They introduced what is called the "multiple tube method." In this method different numbers of tubes containing the same suspension are heated for different times within the range of "skips." They advised the use of great care to avoid the presence of clumps of spores. On account of the important place which this technic has had in applied bacteriology, their description is quoted below verbatim. While their description involves the use of a thermophilic spoilage organism, it may be applied to any organism.

"Several Kolle flasks containing nutrient agar were each inoculated with two ml. of a stock spore suspension of a pure culture of the organism to be tested (in this case, organism 1518). If no stock spore suspension was available, growth from two or more agar slants was suspended in a small amount of sterile distilled water and the resulting suspension used as the inoculum. This suspension was distributed uniformly over the surface of the agar in the Kolle flasks and incubated under optimum conditions (55°C.) for 48 hours. At the end of this incubation period, the bacterial growth in each flask was washed off by the addition of a little sterile water, and the suspension was removed to a sterile flask. Care was taken not to cut the agar and mix any fragments with the bacterial suspension. This resulting suspension was thoroughly shaken and placed again at 55°C. for another 24 hours. Smears from 48-hour cultures showed numerous vegetative organisms and some spores, while stained preparations after the second incubation showed an abundance of spores and fewer vegetative cells. This final suspension was again thoroughly shaken, filtered through a heavy layer of sterile cotton, heated to 90°C. for 10 minutes, to kill the vegetative forms, and again shaken. The suspension was then counted and placed in sterile ampules, which were sealed, and held at ice-box temperature as the stock on which the heat-resistance tests were made. If the suspension was not sufficiently concentrated, it was centrifuged, the supernatant liquid decanted and the spore sediment resuspended and made up to the desired concentration. In some cases, a sand filter was also used and the suspension shaken with sterile sand or glass beads. Plate counts made in triplicate according to standard methods on different suspensions that had received both the above treatment and that filtered through cotton alone showed uniform results without any evidence of clumps. Furthermore, heat-resistance tests on these suspensions prepared by the different methods of filtering showed no indication of variation in this respect.

"After vigorous shaking of the spore suspension in the sealed ampule, the tube was opened aseptically, and definite amounts were inoculated into solutions of different chemical composition, such as M/15 phosphate solution of different pH values (Sorenson mixture of Na_2HPO_4), nutrient broth, pH about 7, and certain food juices, notably canned corn and peas. The concentration of the spores in these solutions was so adjusted that only one or two ml. of the stock spore suspension was added to each 100 ml. of the solution to be heated. In this way the inoculum did not affect the composition of these solutions appreciably nor was the pH value altered. The results thus obtained apply to the conditions under which the spores were heated. After thoroughly shaking, one ml. of these suspensions was inoculated into sterile tubes similar to those used formerly, immediately sealed and heated as usual. The inoculation of these tubes was made from a sterile 10 ml. pipet graduated to .1 ml., and the sealed tubes were held in ice water until heated. The heating of the cultures was carried out as described in the other method. The temperature readings were taken from a Beckmann thermometer and the heat controlled by means of a Sligh thermoregulator. The temperature was kept uniform by means of a turbine stirrer and constant movement of the

125. Williams. 1929. J. Infect. Diseases 44, 421-465.

126. Esty and Williams. 1924. J. Infect. Diseases 34, 516-528.

tubes by hand. Cultures in phosphate solutions were always subcultivated. In the other cases the heated solutions served as culture medium for growth; accordingly, whenever possible the sealed tubes were incubated and growth observed by turbidity and confirmed by production of acid.

"Growth is confirmed by acid production which is determined either by adding two ml. of the stock brom-cresol purple indicator (.4 per cent) to each 100 ml. of the solution containing the spores in which they can grow at the time the solution is inoculated or by emptying the heated contents of the tube after sufficient incubation into .4 per cent of the indicator solution. Subcultures from the phosphate solutions were made in dextrose broth pH 7, to which had been added .4 per cent of brom-cresol purple indicator.

"The addition of this indicator to the solution to be heated does not appear to inhibit the development of viable organisms but it does affect slightly the hydrogen-ion concentration of the solution and the heat resistance. This phase will be discussed further in a subsequent paper. In view of the fact that material in which spores of this organism have grown and produced acid may show no viable organisms after the third day of incubation, and after the fourth day consistently no growth, making recovery of this organism impossible, it is essential that some criterion be found to determine whether or not growth did occur. On this basis, heated cultures of acid-producing organisms should be tested for acid production by using brom-cresol purple indicator either in the medium used for subculturing or by emptying the contents into this indicator solution after sufficient incubation. These methods give clear-cut results and afford an easy means for determining the growth of this organism."

Dickson and Burke's ¹²⁷ Method for Determining the Thermal Death Time of Spores of *Clostridium botulinum*. As a result of the difficulty in preventing spoilage of a small percentage of tubes in the method for determining thermal death time recommended by Bigelow and Esty, a method was devised which was said to eliminate all possibility of contamination of the contents of the tubes after they have been subjected to the required amount of heat. The technic is as follows:

"Three ml. of a one per cent glucose peptic digest liver broth adjusted to a final pH of 7.3 to 7.5 is placed in a soft glass tube 10 by 150 mm., and covered with a thin layer of oil ¹²⁸ to prevent evaporation. The medium is sterilized at 15 lb. pressure for 30 minutes. Immediately before inoculation the tubes of broth are exposed to live steam for 20 minutes to expel the air, and a known number of spores is then added to each tube in .5 ml. of the medium in which they have grown. The tubes are then sealed in an oxygen flame and are ready for heating by immersion in racks into oil which is maintained at the required temperature and vigorously agitated. At the end of the heating period the tubes are removed from the oil, placed in deep pans of cold water to cool, immediately labelled, and then incubated at 37°C. (98.6°F.).

"Incubation is continued for at least 10 days after growth is recognized, in order to allow time for the formation of toxin. The tubes are then opened under sterile conditions, deep agar, broth, and meat mediums are inoculated, and guinea pigs are immediately injected. No test is considered positive unless the broth culture within the sealed tube contains a virulent botulinus toxin at the time the tube is broken."

Magoon's ¹²⁹ Method for Determining the Thermal Death Time of Bacterial Spores. Magoon's method involved the use of capillary tubing. On account of the work by Esty and Cathcart, ¹³⁰ showing that soft glass tubes might yield sufficient alkali to affect the results, "Pyrex" tubing was used. Tubing with an internal diameter of four mm. was drawn out to capillaries of one to 1.5 mm. internal diameter; these were cut into lengths of nine to 10 cm. and the ends sealed immediately in the flame in order to

127. Dickson and Burke. 1921. Proc. Soc. Exper. Biol. & Med. 19, 99-100.

128. Recent work in the field of food bacteriology indicates that oil may have a protective action on bacterial spores when they are exposed to heat. This fact should be borne in mind when this technic is followed. Until more is known about the survival of microorganisms heated in oil, perhaps the oil should not be added.

129. Magoon. 1926. J. Infect. Diseases 38, 429-439.

130. Esty and Cathcart. 1921. J. Infect. Diseases 29, 29-39.

keep the interior sterile. The tubes were kept in a glass stender dish in alcohol. As each was needed, it was picked out with freshly flamed forceps, the alcohol burned off to sterilize the outside, and the sealed tips clipped off by means of a special instrument freshly sterilized in the flame. One end of the tube is then dipped into the spore suspension which rises in the tube by capillary attraction. When sufficient liquid has been taken into the tube, it may be centered so as to leave a free space at each end. The ends of the tube may then be sealed. As soon as the ends are tipped, drop the sealed tubes into cold potassium dichromate-sulfuric acid cleaning solution and let them stand for a few minutes in order to destroy any spores which may adhere to the outside of the tubes. The tubes should be kept cold to prevent the germination of the spores.

To make the test, Magoon heated five of the suspension charged tubes in an electrically controlled oil bath. At the end of the exposure, the tubes should be placed in fresh acetone to dissolve the oil. They may then be stored in alcohol until inoculations are made into nutrient media.

The sterility tests are made by breaking the sterilized capillary tube in the medium. Magoon described his technic for this as follows: The capillary tubes were withdrawn from the alcohol with sterile forceps; without flaming, one sealed tip was removed with a freshly flamed clipper. The open end is then inverted over the mouth of the culture tube from which the cotton plug has been removed and the upper tip of the capillary snipped off. At the same instant the capillary tube is dropped into the culture tube. These simple operations must be rapidly performed.

Williams, Merrill, and Cameron's¹³¹ Apparatus for Determination of Spore-Destruction Rates. This apparatus was developed to yield information on destruction rates rather than absolute death times. It permits heating under pressure of a mass suspension of spores in almost any menstruum and withdrawal of test samples without disturbing the heating test. Anyone familiar with the older methods will recognize the advantages of the new apparatus. The early predictions of those who developed the method have been fully justified by results over recent years. They have been able to obtain reproducible destruction-rate curves and satisfactory thermal death-time curves.

THE THERMAL DEATH-TIME CURVE

For some time canning technologists and others who have had to study heat resistance of bacterial cells and spore suspensions, have plotted the data secured on semilogarithmic paper to secure what is called a thermal death-time curve. No attempt will be made here to show the development of this procedure for it may be found in the literature, especially in papers of Bigelow and Esty,¹³² Ball,¹³³ and Townsend, Esty, and Baselt.¹³⁴

The thermal death-time curve approximates a straight line on semilogarithmic paper. From Ball's¹³³ work and much other work since then which has been based on it, two factors have resulted which mathematically describe the thermal death-time curve. They were described by Townsend *et al.*¹³⁴ as follows:

F—The number of minutes required to destroy the organism (in any specific medium) at 121.1°C. (250°F.).

131. Williams, Merrill, and Cameron. 1937. Food Research 2, 369-375.

132. Bigelow and Esty. 1920. J. Infect. Diseases 27, 602.

133. Ball. 1927. The Canner, Jan. 22, 1927; Univ. Cal. Pub. in Pub. Health 1 (1928), No. 2; 1923. Nat. Res. Council Bull. 37.

134. Townsend, Esty, and Baselt. 1938. Food Research 3, 323-346.

It is obvious that the value of F will depend on the food.

z —The slope of the thermal death-time curve expressed as degrees F. (This is the interval in temperature required for the line to pass through one log cycle on semilogarithmic paper.)

This is an important value and for process calculations of nonacid foods, excepting milk, has generally been given a value of 18. They should be identical for each food but will vary with the food under study. Town-

FIG. 1. Ideal Thermal Death Time Curve for *Clostridium botulinum*. (After Ball.¹²¹)

send, Esty, and Baselt¹³⁴ corrected the z value for the ideal thermal death-time curve to 17.6. This value for z has generally been used for calculating processes for all nonacid foods, with the exception of milk. Competent bacteriologists, however, familiar with the various factors which influence thermal death times, know that it would vary for each food and even for some of the conditions under which it was heated. It is, therefore, recognized that this value should be determined for each food.

Townsend, Esty, and Baselt¹³⁴ discussed this as follows:

“These two factors, being a point and a slope, determine the thermal death-time curve precisely. The value of *F* is the thermal death time at 250°F. and, when the *z* values are identical, is used to compare the resistance of organisms. If the *z* values are not identical, however, this comparison is invalid, since the ratio of the resistance will vary throughout the temperature range. The *z* value measures the change in thermal death time with changing temperature. As the *z* value diminishes, the effect of temperature change becomes more marked.

“This can be seen in the following processes calculated for the same can of food, comparing the *z* values of 14 and 22. The value of *F* is taken as five minutes (250°F.) in both cases:

PROCESS TIME		
<i>z</i>	Retort temperature 121.1°C.(250°F.)	Retort temperature 110°C.(230°F.)
14	5.11 minutes	138 minutes
22	5.47 minutes	44 minutes

The can temperature at the start of the process was 65.6°C.(150°F.). The heat-penetration factors are *fh* = 3 and *j* = 1.20, according to Ball (1928).¹³³

“Owing to variations in heat resistance of suspensions of spores and influence of the medium upon this resistance, the practice was adopted of heating them in a standard phosphate solution (M/15 Na₂HPO₄ and M/15 KH₂PO₄ mixed to give a pH of 7.0) as well as in the particular food under consideration. This permits a comparison of suspensions on a common basis.

“If the *z* values are identical the ratio

$$\frac{\text{Resistance in food}}{\text{Resistance in standard phosphate}}$$

may be used. This is known as the food phosphate factor and, while useful, is justifiable only when the *z* values coincide.”

This investigation was undertaken by Townsend, Esty, and Baselt¹³⁴ to determine the direct thermal death time of *Clostridium botulinum* in foods and to compare it with the thermal death time of Cameron’s organism No. 3679. The latter has been much used as a test organism in experimental packs of canned foods.

The “Thermal Death Time Curve” and “Rate of Destruction Curve” in Figs. 1 and 2 show the method of recording results of thermal death time determinations.

Thermal Death-Time Curve for *Clostridium Botulinum*. Owing to the importance of this anaerobic organism to canned foods and the great heat resistance of its spores much attention has been given to the effect of processing on it. Townsend, Esty, and Baselt¹³⁴ conducted an investigation to determine direct thermal death-time data on *Clostridium botulinum* in various foods and to compare Cameron’s organism No. 3679 with it as far as heat resistance is concerned. The latter organism is almost identical with *Clostridium botulinum*, type C. with exception of formation of toxin. Consequently, it is often used in experimental work where the former cannot be used.

Esty and Meyer¹⁰⁴ were among the first to report extensive data on the heat resistance of spores of *Clostridium botulinum*. One important

observation was that the heat resistance of spores of this organism varied considerably—even spores from the same strain. While some of the factors are known, Esty and Meyer suggested that others were unknown. Heat resistance of spores of *Clostridium botulinum* in 17 varieties of canned food juices showed a variation from less than 10 minutes to 230 minutes at 100°C.(212°F.). The importance of using the right medium for spore production was brought out in this investigation. Esty and Meyer reported that spores generated in different flasks of the same medium but prepared

FIG. 2: Rate of Destruction Curve for Organism 1518 (Flat Sour Producing Organism in Non-Acid Canned Foods). Temperature of Heating 104.4°C.(220°F.). (After Ball.¹²¹)

and handled in exactly the same manner may produce spores with striking differences in heat resistance.

Townsend, Esty, and Baselt¹³⁴ made their observation on suspensions of spores of two strains of *Clostridium botulinum*. They found the heat resistance of this organism in canned foods to be different from that in neutral phosphate. The z values in food media were said to lie in the range 13.4 to 15.6 as contrasted with the range 16.5 to 18.0 in neutral phosphate. The heat resistance of Cameron's organism No. 3679* were

* These numbers refer to certain spoilage microorganisms which have been used in the field of canned food technology. They are described in Chapter 23.

found to be unlike those of *Clostridium botulinum* in food media but are nearly similar in neutral phosphate. The *z* values of No. 3679 are higher in food media than the *z* values of *Clostridium botulinum*. Townsend, Esty, and Baselt¹³⁴ confirmed the work of Esty and Meyer¹⁰⁴ on heat resistance of *Clostridium botulinum* referred to above. They corrected the factors for the ideal thermal death-time curve of *Clostridium botulinum* in neutral phosphate, as determined by Esty and Meyer,¹⁰⁴ to $F' = 2.45$ and $z = 17.6$.

Most of the work on heat resistance of *Clostridium botulinum* has been done at temperatures of boiling water or above, at normal atmospheric pressure (sea level). Comparative data on the amount of heat required to destroy *Clostridium botulinum* at various temperatures and pH were reported by Halversen and Hays.¹³⁵

TABLE 1

Time in Minutes to Destroy Spores of Clostridium botulinum at Varying pH Values and Temperatures (After Halversen and Hays¹³⁵)

Foods	pH	90°C. (194°F.)	95°C. (203°F.)	100°C. (212°F.)	105°C. (221°F.)	110°C. (230°F.)	115°C. (239°F.)

Use of thermal death-time curves in calculating processes rests on the assumption that they are straight lines on semilogarithmic paper. This was believed to be the case by Bigelow¹³⁶ and others. Later it was discovered that they were not always straight lines but showed significant deviations. Rahn¹³⁷ also pointed out this fact.

Thermal death-time curves may be drawn from data collected in only two determinations at different temperatures, i.e., from two points. Curves drawn from some thermal death-time data have not been straight lines, and those who wish to use them in computing processes have had to approximate a straight line using some part of the actual curve. An error may be introduced because one may not know what part of the curve should be chosen for determining the curve finally adopted. Whether the practice to “straighten a curve” is sound is quite doubtful. Perhaps it is wrong to always expect and demand a straight-line curve.

Dormancy or Delayed Germination of Spores. Numerous observations have shown in recent years that spores may not germinate even under what would ordinarily be called ideal conditions. This was first observed

135. Halversen and Hays. 1936. J. Bact. 32, 466; Idaho Agr. Exp. Sta. Bull. 221 (1937) 26, 27.

136. Bigelow. 1921. J. Infect. Diseases 29, 528-536.

137. Rahn. 1930. J. Gen. Physiol. 13, 395.

with spores which had been heated and it was suggested that their delayed germination was due to heat injury. When it was observed that unheated spores might also show dormancy, this explanation was abandoned.

Dickson *et al.*¹³⁸ noticed dormancy with the spores of *Clostridium botulinum*. Burke, Sprague, and Barnes¹³⁹ stated that the spores of common aerobic bacteria could lie dormant for months under favorable growth conditions. Spores of *Bacillus subtilis* and *Bacillus megatherium* remained dormant for 39 and 90 days, respectively. Burke¹⁴⁰ had previously reported dormancy of a small percentage of the spores of *Clostridium botulinum*. Williams,¹⁴¹ who could not observe the phenomenon with *Bacillus subtilis*, has reviewed most of the literature. The possibility of dormancy makes it necessary to hold subcultures for a sufficiently long time before negative growth is reported. The phenomenon may also be important in foods which are heated for preservation but which are not sterilized. Such is the case with canned foods which are "commercially sterilized." The microorganisms may be dormant and develop later if the cans are stored under suitable conditions.

Preservation of Microorganisms. In several applications of bacteria to food investigations, it is necessary to preserve cultures of microorganisms. This is the case with species which are to be used in dairy starters, pure-culture inoculum for making vinegar, etc. A number of methods have been proposed. Hansen¹⁴² suggested the use of 10 per cent sucrose solution for preserving yeasts. A small amount of the culture was added to the sterilized solution. Tanner and Burrows¹⁴³ found that this method was unsatisfactory for some species, even though Klöcker¹⁴⁴ had reported that yeasts could be preserved in this manner for 25 years. Swift¹⁴⁵ suggested a method based on freezing to dry the cells, which were to be preserved. Thaysen¹⁴⁶ kept bacteria for long periods without frequent transferring, by adding a little calcium carbonate or calcium diphosphate to a culture which had been allowed to grow vigorously. A second method was suggested for sporeformers, involving the use of dry sterile sand. In both cases, the tubes were sealed in the flame for storage. Barthel¹⁴⁷ suggested sterilized soil in Freudenberg flasks as a good medium for keeping yeasts and fermentation organisms. This method has been used for storage of certain organisms concerned in spoilage of canned foods. Other methods have been proposed by Sartory and Mahen,¹⁴⁸ Kiefer,¹⁴⁹ and Truche.¹⁵⁰

Sartory and Mahen found some broth cultures sealed in tubes to be viable after 16 years.

von Daranyi¹⁵¹ sealed his cultures with sterilized liquid paraffin. His cultures are grown on 45°C.(113°F.) agar-slants and paraffin is poured over them sufficient to cover the upper end of the slant to a depth of several millimeters with tube held upright. When it is necessary to use the sealed culture, the tube is slanted in the opposite direction, so as to expose part of the surface of the culture without drawing off the paraffin. The author claims a considerably longer period of viability for cultures so treated than for those under ordinary conditions.

Swift¹⁵² again discussed his method, the principle of which consists of the removal of water while the cells are frozen, either by a chemical desiccant or by low-temperature evaporation and condensation. The former method is simpler for cultures. Young cultures grown in broth were centrifuged and resuspended in a small amount of the same medium. This suspension was distributed in tubes and frozen under vacuum. All investigators are not agreed that this is the best method. Morton and Pulaski¹⁵³ studied three methods—storage of broth cultures in sealed ampoules, agar-slant cultures overlaid with paraffin oil, and the freezing-drying method. The second method, in which growth on agar slants is covered with sterile paraffin oil, gave best results. A heavy mineral oil is most suitable, and it must fill the tube to a point one centimeter above the top of the slope. The oil should be sterilized in the oven at 150 to 170°C.(302 to 338°F.) for one hour, as it becomes mixed with water if autoclaved.

GROUPS OF BACTERIA OF SPECIAL INTEREST TO FOOD BACTERIOLOGY

The arrangement of bacteria into groups has been done mostly for convenience. In some instances, probably, these groups are made up of very closely related organisms; in other cases too insignificant characteristics have been taken. As mentioned above, many of the groups are arbitrary and often depend upon characteristics which are not fixed. Many of the groups need to be subjected to careful study. This will tell whether they approach natural units and, if they do, the relation and characters of the members. The groups of pathogenic bacteria and those which have sanitary significance have already received careful study.

The groups which are treated in the following pages are those frequently encountered by the food microbiologist. A discussion of all of the larger groups would be unnecessary.

Aerobic Sporeforming Group. These bacteria cause the food preserver little trouble. Their spores are not especially heat resistant and do not ordinarily survive processes given canned foods. They do appear, however, in some of the foods preserved by other methods.

151. von Daranyi. 1928. *Centbl. Bakt.* Pt. 1, Orig. 108, 160-162.

152. Swift. 1937. *J. Bact.* 33, 411-421.

153. Morton and Pulaski. 1938. *J. Bact.* 35, 163-566.

Many different aerobic sporeforming bacteria have been described in the literature. To Ford ¹⁵⁴ and his colleagues, we are indebted for an analysis of the nonpathogenic, aerobic, sporeforming bacilli. Ford mentioned the chaotic condition in which these bacteria were grouped. Almost any large aerobic sporeformer would be called *Bacillus subtilis* although the organisms isolated by different investigators might have little in common. From a study of more than 1,700 cultures from different sources, Ford made the following groups for his sporeformers:

GROUP I. SUBTILIS GROUP.

Small, homogeneous, sluggishly motile organisms, measuring .375 by 1.5 to 2.5 microns. No threads on glucose agar. Central or excentric spores, oval, measuring .5 by .75 to .875 micron, often retaining tags of protoplasm. Growth on solid media hard and penetrating with tenacious scums on fluid media.

Represented by:

Bacillus subtilis Cohn.

Bacillus subtilis-viscosus Chester.

GROUP II. MENTERICUS GROUP.

Small, homogeneous, actively motile organisms, measuring .5 by 2 to 4 microns. Often produce long threads on glucose agar. Spores measure .5 by 1 to 1.125 microns, oval, retaining terminal tags of protoplasm. Growth on hard media as soft pultaceous mass with tendency to wrinkle, on fluid media as friable, easily broken scums.

Represented by:

Bacillus vulgatus (Flügge) Trevisan.

(*Bacillus mesentericus vulgatus* Flügge.)

Bacillus mesentericus (Flügge) Migula.

(*Bacillus mesentericus fuscus* Flügge.)

Bacillus atterimus Lehmann and Neumann.

(*Bacillus mesentericus niger* Lunt.)

Bacillus globigii Migula.

(*Bacillus mesentericus ruber* Globig.)

Bacillus niger Migula.

(*Bacillus lactis niger* Gorini.)

Bacillus mesentericus var. *flavus*

Bacillus panis Migula.

(*Bacillus mesentericus panis viscosi* I Vogel.)

(Motility lost by capsule formation.)

GROUP III. COHAERENS-SIMPLEX GROUP.

Motile organisms, somewhat larger than either *Bacillus subtilis* or *Bacillus mesentericus*, measuring .375 to .75 by .75 to 3 microns. Thicker and longer forms on glucose agar. Involution forms and shadow forms common and appear early. Spores cylindrical, measuring .5625 to .75 by 1 to 1.5 microns. Growth as a soft mass on hard media, as turbidity with little or no scum on fluids.

Represented by:

Bacillus cohaerens Gottheil.

Bacillus simplex Gottheil.

Bacillus agri Ford.

GROUP IV. MYCOIDES GROUP.

Large organisms with square ends growing in long chains. Single cells measure .5 to 3 to 6 microns. On glucose agar organisms are thicker and longer and made up of

154. A series of papers was published by Ford and his colleagues in the *Journal of Bacteriology* 1 (1916), 273-319. These descriptions are taken from these papers.

globular bodies. Tendency for organisms to grow in curves or spirals. Spores central or excentric, round or oval to cylindrical measuring .75 to 1 to 2 microns. Spores vary greatly in size and often appear in chains. Growth on hard media dry and penetrating, on fluid media as firm, tenacious scum.

Represented by:

Bacillus mycoides Flügge.

Bacillus prausnitzii Trevisan.

(*Bacillus ramosus liquefaciens* Prausnitz.)

Bacillus adhaerens Ford.

(No motility.)

GROUP V. CEREUS GROUP.

Large, motile organisms with round ends, measuring .75 by 2.25 to 4 microns. Tend to grow in short chains. Thicker and longer on glucose agar where protoplasm is converted into globular bodies. Central or excentric spores, cylindrical, measuring .5 to .75 by 1.125 to 1.5 microns. Spores retaining protoplasm at one or both ends often resembling enlarged subtilis or mesentericus spores. Growth on hard media as soft, pultaceous mass with tendency to fold or wrinkle, on fluid media as thick, friable scum.

Represented by:

Bacillus cereus Frankland.

Bacillus albolactus Migula.

Bacillus cereus var. *fluorescens* Ford.

GROUP VI. MEGATHERIUM GROUP.

Very large, actively motile organisms, measuring .75 to 1.25 by 3 to 9 microns. Often in long forms which spread out, lose their cytoplasm, and show peculiar aggregations of protoplasm at their periphery. Protoplasm rapidly converted into peculiar globular, highly refractive bodies, particularly on glucose agar. Shadow and transparent forms appear early. Spores central, excentric or subterminal, oval to cylindrical, measuring usually .75 to 1.125 by 1.5 to 2 microns. Spores vary greatly in shape, sometimes round, sometimes rectangular, often reniform. Growth on solid media as thick, pultaceous mass, on fluid media as turbidity with little or no scum formation.

Represented by:

Bacillus megatherium DeBary.

Bacillus petasites Gottheil.

Bacillus ruminatus Gottheil.

GROUP VII. ROUND TERMINAL SPORE GROUP.

Small, actively motile organisms, measuring .5 to .75 by 1.5 to 3 microns, often forming long threads in old cultures. Protoplasm homogeneous. Spores subterminal or terminal, round, thicker than the organisms from which they spring, measuring 1 to 1.5 microns in diameter.

Represented by:

Bacillus pseudotetanicus (Kruse) Migula.

Bacillus fusiformis Gottheil.

GROUP VIII. CYLINDRICAL TERMINAL SPORES GROUP.

Small, thin, actively motile organisms, measuring .375 to .5 by 2.5 to 4 microns. Slightly larger on glucose agar but no changes in character of protoplasm. Spores terminal, cylindrical, measuring usually .75 by 1.125 to 1.5 microns.

Represented by:

Bacillus circulans Jordan.

Bacillus brevis Migula.

Bacillus terminalis Migula.

GROUP IX. CENTRAL SPORED GROUP.

Long, actively motile organisms with pointed ends, measuring .375 to .5 by 1.125 to 4 microns. Slightly larger on glucose agar, but no change in character of protoplasm. Spores develop in the middle of the rods which become spindle-shaped. Spores large, cylindrical, measuring .625 to .875 by 1.125 to 1.5 microns.

Represented by:

Bacillus centrosporus Ford.

Bacillus laterosporus Ford.

The species characterization of these bacteria appears in the author's "Bacteriology."

Bergey's "Manual of Determinative Bacteriology," fifth edition, 1939, lists descriptions of many species of aerobic, sporeforming bacteria.

One species, *Bacillus betanigrificans*, first described by Cameron, Esty, and Williams¹⁵⁵ as the cause of blackening of canned beets, probably belongs in this group. This organism is facultative with respect to oxygen and produces spores which probably explain its resistance to heat.

Heat-resistance observations were made using the method of Esty and Williams.¹²⁶ At 110°C. (230°F.), using a concentration of spores of 150,000 per ml. in phosphate buffer solution (pH 7.0) and in beet juice (pH 5.5), survival in the former was 20 minutes and destruction 25 minutes; in beet juice no survival was observed in the shortest heating time of five minutes.

THE COCCACEAE

The Coccaceae have been studied by Hucker.¹⁵⁶ Into the group were placed most of the bacteria with round cells, irrespective of the space arrangement of the cell masses. Hucker believed that Micrococci Rhodococci, and Staphylococci could be placed in one genus for which the name Micrococci was retained. The group was characterized as follows:

Micrococcus (Cohn, 1872): Cell division in two or three planes. Generally does not produce regular tetrads or packets. Typically saprophytic or a facultative parasite. May or may not produce red, yellow, or orange pigment. Produce moderate to abundant growth on ordinary nutrient media. Gram-positive, variable, or negative. Aerobic or a facultative anaerobe. Does not produce indol. Gelatin often liquified. Rarely attacks starch. True endospores have not been found. Nitrates often reduced. Motile species have been described. Produces acid but rarely gas from the fermentation of sugars.

After studying a great number of coccus forms, Hucker prepared the following key:

The term *Micrococcus* has been employed to designate the genus of irregular mass-forming cocci and, after a study of a long series of cultures, 16 species have been found which appear to be more or less constant. Gelatin liquefaction, nitrate reduction, and ability to utilize certain ammonium salts as the only source of nitrogen have served as the most important basis for the differentiation of these species. The species of this genus may be outlined as follows:

KEY TO THE SPECIES OF THE GENUS MICROCOCCUS.

A. Pigment produced.

I. Yellow pigment produced.

1. Gelatin liquefied.

a. Nitrates reduced.

* Utilizes $\text{NH}_4\text{H}_2\text{PO}_4$ as a source of nitrogen.

M. conglomeratus

** Does not utilize $\text{NH}_4\text{H}_2\text{PO}_4$ as a source of nitrogen.

M. citreus

155. Cameron, Esty, and Williams. 1936. Food Research 1, 73-85.

156. Hucker. 1924. N. Y. Agr. Exp. Sta. Bulletins 135, 136, 141, 142, 143, 144.

b. Nitrates not reduced.

M. flavus

II. Red pigment produced.

1. Gelatin liquefied.

M. roseus

2. Gelatin not liquefied.

M. cinnebareus

III. Orange pigment produced.

1. Gelatin liquefied.

M. aureus

2. Gelatin not liquefied.

M. aurantiacus

B. No pigment produced.

I. Cells in irregular masses.

1. Gelatin liquefied.

a. Nitrates reduced.

* Utilizes $\text{NH}_4\text{H}_2\text{PO}_4$ as a source of nitrogen. Acid proteolytic action upon milk.

M. casei

** Does not utilize $\text{NH}_4\text{H}_2\text{PO}_4$ as a source of nitrogen.

M. albus

b. Nitrates not reduced.

* Utilizes urea as a source of nitrogen.

M. ureae

** Does not utilize urea as a source of nitrogen.

M. freudenreichii

2. Gelatin not liquefied.

a. Nitrates reduced.

M. epidermis

b. Nitrates not reduced.

M. candidus

II. Cells in definite tetrads.

M. tetragenus

The Genus *Leuconostoc*. Members of this genus have been encountered by bacteriologists in various fields. They were encountered by early investigators as the causes of gum formation in sugar factories; they have also been isolated from numerous food products. Food bacteriologists are indebted to Hucker and Pederson¹⁵⁷ for a report on this genus. They observed sufficiently fundamental physiological characteristics to justify a genus for which the name *Leuconostoc* was said to have priority. Morphologically the genus is intermediate between the streptococci and lactobacilli. Hucker and Pederson classified the genus as follows:

CLASSIFICATION OF THE GENUS *LEUCONOSTOC* *LEUCONOSTOC* VAN TIEGHEM, 1878 EMEND

"Cells normally occurring as spheres. Under certain conditions, such as in acid fruits and vegetables, the cells may lengthen and become pointed or even elongated into a rod. Grows on ordinary media, but growth is enhanced by the addition of yeast cells, extract of yeast or other vegetable tissues. Generally produces a limited amount of acid. Rarely curdles milk. Produces mannitol from fructose. By-products of the

157. Hucker and Pederson. 1930. N. Y. Agr. Exp. Sta. Tech. Bull. 167.

fermentation of glucose include carbon dioxide, lactic acid, acetic acid, and ethyl alcohol. Approximately one-fourth of the glucose fermented is converted to carbon dioxide. Levo-lactic acid is always produced and sometimes dextro-lactic acid. Gram positive. Nonmotile. Certain types grow with characteristic slime formation in sucrose media. Ordinarily does not increase the amount of soluble nitrogen in medium even after long periods of incubation.

"Synonyms:

Lactococcus Beijerinck 1912 (pro parte).

Betacoccus Orla-Jensen 1919.

"Type Species:

"1. *Leuconostoc mesenteroides* (Cienkowski 1878) Van Tieghem 1878.

"Produces slime from sucrose. Ferments xylose or arabinose, fructose, glucose, mannose, galactose, sucrose, and generally raffinose, salicin, lactose, and mannitol. Rarely ferments dextrin, starch, inulin, sorbitol, rhamnose, or glycerol. Grows quickly in sucrose gelatin and produces characteristic growth. Most active of the genus. Generally encountered in vegetable and other plant materials. Frequently isolated from slimy sugar solutions. Optimum growth temperature 21°C.

"Synonyms:

Leuconostoc aller Zettnow 1907.

Leuconostoc opalanitza Zettnow 1907.

Betacoccus arabinosaceus Orla-Jensen 1919.

Leuconostoc pleofructi (Savage and Hunwicke) Pederson 1929 A.

Ninety-seven strains of this species were investigated, fifty-eight of which were studied in detail. Among the well-authenticated cultures coming within the confines of this description are *Leuconostoc pleofructi*, *Betacoccus arabinosaceus*, *Betacoccus* No. 12 (Orla-Jensen) and *Betacoccus* No. 11 (Orla-Jensen).

"*Leuconostoc mesenteroides* is the most active species of the genus and is generally associated with vegetable and other plant materials.

"2. *Leuconostoc dextranicus* (Beijerinck, 1912) Comb. nov.

"Produces slime only in rapidly growing cultures. Ferments sucrose, glucose, galactose, maltose, levulose, and generally lactose and mannose. Does not ferment xylose or arabinose, glycerol, rhamnose, sorbitol, mannitol, starch, rarely raffinose, inulin, dextrin. Found both in plant materials and in milk products. Optimum temperature of growth 21 to 25°C.

"Synonyms:

Lactococcus dextranicus Beijerinck 1912.

Betacoccus bovis Orla-Jensen 1919.

Streptococcus kefir Migula 1900 emend. Evans 1918.

Streptococcus paracitrovorus Hammer 1920 A.

"Thirty-four strains of *Leuconostoc dextranicus* were available for study, 14 of which were studied in detail. A culture of *Streptococcus citrovorus* was found to be included in this group as well as a strain of *S. paracitrovorus*.

"*Leuconostoc dextranicus* is much less active in almost every respect than *L. mesenteroides*, and is not as commonly encountered. The two types, however, are quite distinct and may be differentiated with certainty by the fermentation of pentoses.

3. *Leuconostoc citrovorus* (Hammer 1920 A) Comb. nov.

"Grows poorly on ordinary media without the addition of yeast extract or other growth accessory substance. Produce acid from fructose, glucose, galactose, lactose. Generally does not produce acid from glycerol, xylose, arabinose, rhamnose, sorbitol, mannitol, sucrose, mannose, maltose, raffinose, inulin, dextrin, starch, or salicin. Found in milk and dairy products. Optimum temperature from 20 to 25°C.

"Synonyms:

Streptococcus citrovorus Hammer 1920 A.

Betacoccus cremoris Soncke Knudsen and Sorensen 1929."

Bergey's "Manual of Determinative Bacteriology," fifth edition, described 46 species of *Micrococcus* and nine of *Staphylococcus*. Aerobic, sporeforming bacteria are not especially heat resistant and consequently are of little significance as spoilage organisms. Three species of *Leuconostoc* were recognized: *Leuconostoc mesenteroides*, *Leuconostoc dextransicum*, and *Leuconostoc citrovorum*. Spiegelberg¹⁵⁸ found *Leuconostoc mesenteroides* to be one of the causes of bursting swells in canned pineapple.

THERMOPHILIC BACTERIA

Thermophilic bacteria are important organisms in spoilage of canned foods. The literature has become quite large and was reviewed by Morrison and Tanner¹⁵⁹ and by Robertson.¹⁶⁰ The term "thermophilic" comes from the Greek words meaning "heat loving." The optimum temperature for growth is around 55 to 60°C. (130 to 140°F.). The first work on thermophilic bacteria was done on strains from soil, water, etc. In 1879, Miquel described a strain to which he gave the name *Bacillus thermophilus*. Since then the thermophilic bacteria have been shown to be of great significance in the canned food, sugar, and dairy industries. The reader is referred to Chapters 5 and 23 of this book and to the publications mentioned above for the literature. This brief discussion of thermophilic bacteria does not indicate that they are relatively unimportant in food bacteriology. With the possible exception of the anaerobic sporeformers, one would find it quite difficult to find a more important group. Since they are discussed fully in other chapters, they will not be considered at great length here.

Some fungi which may cause spoilage in canned foods are also thermophilic. Sartory and Meyer¹⁶¹ isolated such an organism from swelled cans. Its properties were much like *Actinomyces thermophilus*. However, on the basis of its staining properties it was placed with *Mycobacteriaceae* and apparently identified as *Corynebacterium necrophorum*.

THE COLIFORM GROUP

This group of organisms has played a great role in sanitary bacteriology where its most important member, *Escherichia coli*, is the main biological indicator of pollution. Its role in this case has been reviewed in the chapter on "Water Bacteriology" and need not, therefore, be discussed again here. A few other species in the group have roles in the field of food microbiology which makes it desirable to mention their characteristics here. The group has been known under various names. Breed and Norton¹⁶² suggested the term "coliform" to designate the lactose-fermenting, aerobic bacteria used as a measure of pollution of water. It was hoped that, when the same term is applied in milk and oyster examination, it will be used with a similar meaning. Reconsider-

ation of the use of the coliform group as the sole index of dangerous contamination of water supplies was requested.

Bergey's "Manual of Determinative Bacteriology," fifth edition, recognizes but two species in the genus *Escherichia*; these are *Escherichia coli* and *Escherichia freundii*. The definition of *Escherichia coli* for sanitary analysis is *all aerobic and facultative anaerobic Gram-negative, nonspore-forming bacilli which ferment lactose with gas formation* (Standard Methods of Water Analysis).

A critical review of the group was prepared by Parr,¹⁶³ which every one who has any interest whatever in it, should read. This author explained the origin of many of the names which have been used, and stressed the confusion which has resulted from excluding some species. Confusion has been caused in the past by failure to recognize variations which have led to many names and false species. The coliform group was said to be a large one of closely related, highly intergrading, and somewhat unstable bacteria which form a fairly wide gamut or continuum extending from the lactose-negative paracolon forms at one extreme to the highly reactive *Aerobacter aerogenes* at the other. Standing with the paracolon forms next to *Salmonella* one finds the Morgan bacillus. In about the same positions, and leading to *Eberthella* and *Shigella*, are located the anaerogenous *Escherichia coli*. Next to these varieties come the slow lactose-fermenting *Escherichia coli* so likely to be manifested as "unstable variants." Completing one side of the picture, one finds the typical *Escherichia coli* which bridge over to the *Aerobacter aerogenes* side by way of the "intermediates." Below *Aerobacter aerogenes* we find *Aerobacter cloacae* which appears to point toward the genus *Proteus*, and, above all forms but particularly above *Aerobacter aerogenes*, are located the Friedlander organisms.

In an ecological study of the coliform group, Griffin and Stuart¹⁶⁴ isolated 6,500 strains from various sources. *Escherichia* strains were said to be normal inhabitants of feces while *Aerobacter* strains are typical of non-fecal materials. Griffin and Stuart admitted that the latter might, at times, be found in fecal materials but considered this occurrence to be adventitious.

Not many investigators have attempted to determine the possible relationship of the important members of the coliform group. It is reasonable to assume that they have developed from one another because their characteristics are so much alike. Horwood and Webster¹⁶⁵ believed that they had observed a transformation of *Aerobacter aerogenes* into *Escherichia coli* in the human intestine and that the former organism might have more sanitary significance than is generally accorded to it.

Weldin¹⁶⁶ prepared a classification and key to genera of coliform bacteria and some of the pathogens related to them.

THE LACTIC ACID-PRODUCING BACTERIA

While much has been written on the lactic acid-producing bacteria, few complete characterizations of species have been published. Henneberg¹⁶⁷ and Orla-Jensen¹⁶⁸ described a few of the many species which are included in this group. Several of the more common species are described in the chapter on "Milk and Milk Products." They play important roles in many places in food bacteriology.

Several lactobacilli have been isolated from spoiled fruit juices and tomato products. These are discussed in the several chapters on these products in this book. They are also important in butter cultures.

They have been studied from the taxonomic viewpoint by several investigators. Kitahara¹⁶⁹ claimed to have isolated about all of the known species and presented a classification based on his work. His conclusions in some places conflict with those of Shimwell¹⁷⁰ who studied the lactic acid bacteria of beer. Both of these investigators reported new strains which should be of interest to food bacteriologists.

ANAEROBIC BACTERIA

Anaerobic bacteria have not received the attention which is due them in food bacteriology. Special methods are required for cultivating them, many of which are not adapted to routine work.

Anaerobes are significant only as spoilage organisms. *Clostridium botulinum*, in addition to its ability to spoil foods, also produces a powerful toxin and is, therefore, the best example of an organism which causes food poisoning. *Clostridium putrificum* causes trouble in the meat-preservation industry. Other anaerobic sporeformers are mentioned at various places in this book, especially in Chapter 23. Canned foods are subject to considerable spoilage by these forms.

Several reviews of the anaerobes have been published, from which the bibliography of the forms may be secured. Kahn¹⁷¹ studied those from the human alimentary tract. Another excellent report was published by the Special Committee upon Anaerobic Bacteria and Infections, of the Medical Research Committee (Special Report Series No. 39, 1919, of Great Britain). Hall¹⁷² and Spray¹⁷³ have published differential keys to anaerobes. Spray's which is more recent, is given here.

TENTATIVE KEY TO THE SPORULATING ANAEROBES

- I. Iron-Milk, active gaseous fermentation; early coagulation (24-48 hours); no digestion of clot; no blackening:
 - A. Lead Acetate, strongly blackened;
 1. Sucrose fermented; Salicin not fermented.
 Nitrite +; Indol —; Violet —; Gelatin +; Motility —;
 Dextrose +; Lactose +; Sucrose +; Salicin—;
 Spores ovoid, central-excentric, not swelling rod; (spores infrequently observed); not in fermentable sugars;

168. Orla-Jensen. 1919. Mem. Acad. Roy. des Sci. et des Lettres de Danemark 5, No. 2.

169. Kitahara. 1940. J. Agr. Chem. Soc., Japan 16, 137.

170. Shimwell. 1941. Wallerstein Lab. Communications 4, 41-48.

171. Kahn. 1924. J. Infect. Diseases 35, 423-478.

172. Hall. 1922. Idem 30, 445-504.

173. Spray. 1936. J. Bact. 32, 135-155.

1. *Clostridium welchii*

2. Sucrose, not fermented; Salicin, Fermented;
 Nitrite +; Indol —; Violet —; Gelatin +; Motility +;
 Dextrose +; Lactose +;
 Spores ovoid, excentric-subterminal; distinctly swelling rod; (spores infrequently observed, apparently not in fermentable sugars);

2. *Clostridium aerofœtidum*

- B. Lead Acetate, not blackened; no browning;
 Nitrite +; Indol —; Violet —; Gelatin—; Motility +;
 Dextrose +; Lactose +; Sucrose +; Salicin +;
 Spores ovoid, central-excentric, not swelling rod; (spores abundant, even in fermentable sugars);

3. *Clostridium multif fermentans*

- a. Glycerol, fermented;
 b. Glycerol, not fermented*

4. *Clostridium butyricum* Group

II. Iron-Milk, inactive gaseous fermentation; late coagulation at 4-6 days; no digestion of clot; no blackening:

A. Lead Acetate, strongly blackened;

1. Indol, positive;

- Nitrite +; Violet —; Gelatin —; Motility +;
 Dextrose +; Lactose +; Sucrose +; *Salicin +;
 *(pH in sucrose reduced from 7.2 to 6.4 only);
 Spores almost spherical, abundant, subterminal, becoming terminal; swelling rod;
 Vegetative cells distinctly navicular, pointed;

5. *Clostridium sphenoides*

2. Indol, Negative;

- Nitrite +; Violet —; Gelatin —; Motility +;
 Dextrose +; Lactose +; Sucrose +; Salicin +;
 Spores ovoid, excentric-subterminal; swelling rod; (spores infrequently observed, not abundant);
 Vegetative cells slender, round to pointed ends;

6. *Clostridium fallax*

B. Lead Acetate, slight smoky browning; not blackened;

- Nitrite +; Indol —; Violet —; Gelatin —; Motility +;
 Dextrose +; Lactose +; Sucrose +; Salicin +;
 Spores ovoid, terminal, swelling rod; grows aerobically (Micro-aerophile);
 Spores abundant even in fermentable sugars.

7. *Clostridium tertium*

C. Lead Acetate, no blackening; no browning;

- Nitrite +; Indol —; Violet —; Gelatin +; Motility +;
 Dextrose +; Lactose +; Sucrose —; Salicin +;
 Spores ovoid, abundant, excentric-subterminal; swelling rod;

8. *Clostridium septicum*

(Vibrio septique)

(*Clostridium oedematis-maligni*)

III. Iron-Milk, inactive gaseous fermentation; (Long continued)

Late, if any, coagulation (10-20-30 days, or not even at 60 days); no digestion, no blackening;

A. Lead Acetate, strongly blackened;

1. Lactose, not fermented;

- Nitrite —; Indol —; Violet —; Gelatin +; Motility +;
 Dextrose +; Sucrose —; Salicin —;
 Spores ovoid, not abundant, excentric-subterminal, swelling rod;

* In the original publication, Spray quoted McCoy that this was not entirely and uniformly true.

[Some few strains coagulate Iron-Milk (5-12 days), others not 30 days, although gas bubbles are constantly evolved];

9. *Clostridium novyi*
(*Clostridium oedematiens*)

2. Lactose, fermented;

Nitrite +; Indol —; Violet —; Gelatin +; Motility +;

Dextrose +; Sucrose +; Salicin —;

Spores ovoid, abundant, excentric-subterminal, swelling rod;

[Some strains coagulate Iron-Milk (12 days); others not at 56 days];

10. *Clostridium chauvoei*

B. Lead Acetate, no blackening; no browning;

Nitrite —; Indol —; Violet —; Gelatin +; Motility +;

Dextrose +; Lactose —; Sucrose —; Salicin —;

Spores ovoid, not abundant, terminal, slightly swelling rod;

[No coagulation of Iron-Milk (30 days), although gas bubbles are constantly evolved (15-20 days)];

11. *Clostridium luciliae*
(*Clostridium botulinum C*)

IV. Iron-Milk, inactive gaseous fermentation; more or less rapid digestion, with or without previous clotting); strongly blackened, early (48 hours) or late (8-9 days);

A. Lead Acetate, strongly and rapidly blackened (24-48 hours);

1. Salicin, fermented;

Nitrite —; Indol —; Violet +; Gelatin +; Motility +;

Dextrose +; Lactose —; Sucrose —;

Spores ovoid, not usually abundant, excentric-subterminal; swelling rod;

[Iron-milk softly coagulated (2-5 days); first blackened (5-7 days); clot slowly digested at 10-20 days];

(Differentiated by toxin-antitoxin);

12. *Clostridium botulinum (A&B)*

2. Salicin, not fermented (see *Clostridium centrosporogenes*);

a. Vanillin Violet +; Indol —;

Nitrite —; Gelatin +; Motility +;

Dextrose +; Lactose —; Sucrose —;

Spores ovoid, abundant, excentric-subterminal, swelling rod;

[Iron-milk not coagulated, translucent, then flocculent precipitate, rapidly blackened (24-48 hours); rapidly digested (8-10 days)];

1) Tyrosine crystals not observed;

13. *Clostridium sporogenes*

2) Tyrosine crystals in old cultures;

14. *Clostridium tyrosinogenes*

b. Vanillin Violet —; Indol +;

Nitrite —; Gelatin +; Motility +;

Dextrose +; Lactose —; Sucrose —; Salicin —†;

Spores ovoid, abundant, central-excentric; not markedly swelling rod;

1. Pathogenic;

15. *Clostridium sordelli*

2. Nonpathogenic;

16. *Clostridium bifermentans*
(*Clostridium centrosporogenes*)

B. Lead Acetate, not blackened; no browning;

Nitrite —; Indol —; Violet —; Gelatin +; Motility +;

Wine-red color in Iron-Gelatin at 24-48 hours;

Dextrose —; Lactose —; Sucrose —; Salicin —;

(No sugars fermented)

† Five of thirteen cultures studied by Spray and labeled *Cl. centrosporogenes* fermented salicin

Grows aerobically (Microaerophile);

Spores ovoid, abundant, excentric-subterminal, swelling rod;

17. *Clostridium histolyticum*

V. Iron-Milk, no gaseous fermentation; no blackening; no digestion; coagulation late, if any (15-20 days or more):

A. Lead Acetate, not blackened, but showing smoky brown at 24-48 hours; not increased with incubation;

Nitrite —; Indol +‡; Violet —; Gelatin +; Motility +;

Dextrose —; Lactose —; Sucrose —; Salicin —;

(No sugars fermented)

Spores spherical, terminal, swelling rod;

a. Toxic;

b. Nontoxic;

18. *Clostridium tetani*

19. *Clostridium lentoputrescens*
(*Clostridium putrificum*)

B. Lead Acetate, not blackened; no trace of browning;

Nitrite —; Indol +; Violet —; Gelatin —; Motility +;

Dextrose +; Lactose —; Sucrose —; Salicin —§;

Spores spherical to slightly ovoid, terminal, swelling rod;

20. *Clostridium tetanomorphum*.

Brewer¹⁷⁴ reported a clear medium for cultivation of anaerobic bacteria "aerobically." To provide proper oxidation-reduction potential, .1 per cent of sodium thioglycollate was added. Brewer found it unnecessary to use Smith fermentation tubes or other special equipment or to heat the medium just before use. McClung¹⁷⁵ also found this medium to be satisfactory. A special Petri dish cover to be used with the medium has also been devised by Brewer.¹⁷⁴

One objection to Spray's¹⁷³ scheme for the identification of anaerobes, mentioned by Reed and Orr,¹⁷⁶ is the fact that many of the differential reactions require up to two weeks for completion. Introduction of reducing agents into fluid media, such as Brewer's medium has made it possible to secure results more rapidly. Reed and Orr confirmed the utility of such media and arranged a group of diagnostic reactions with these new media which yielded precise results for pathogenic anaerobes in 24 hours. Their system will not be reviewed here because it applies mainly to pathogenic anaerobes.

Other species than those mentioned in Spray's key have become important in the food-preservation industry. *Clostridium nigrificans* (Werkman and Weaver¹⁷⁷) was reported as the cause of sulfide spoilage of canned peas. It brings about a malodorous spoilage accompanied by a blackening and later some disintegration.

Anaerobic, sporeforming, butyric acid-producing bacteria have been troublesome bacteria in canned fruits. *Clostridium pasteurianum* has been

‡ Occasional strains are indol weak or apparently indol negative.

§ Some strains lower pH slightly (from 7.2-6.8).

found in this role by Townsend,¹⁷⁸ Spiegelberg,¹⁵⁸ and others. Spiegelberg reported at great length on the characteristics of strains isolated from canned pineapple. They were essentially like the strain of *Clostridium pasteurianum* first described by Winogradsky.

CULTIVATION OF ANAEROBIC BACTERIA

Anaerobic bacteria are quite important in many foods because of the fact that they are hard to kill and are able to grow in closed containers. Knowledge concerning these important organisms has been greatly amplified during the past few years by Hall,¹⁷⁹ Heller,¹⁸⁰ Kahn,¹⁸¹ Weinberg and Ginsbourg,¹⁸² and many others. It is not a simple matter to secure pure cultures of these organisms. Barber,¹⁸³ Hall,¹⁷⁹ Kahn,¹⁸¹ and Kendall *et al.*¹⁸⁴ advised the isolation of the single cells for pure cultures.

Several indicators have been used by those who have worked with anaerobes, to determine the oxygen tension of various anaerobic methods. Hall¹⁷⁹ used methylene blue. It is colorless in the absence of oxygen and blue in its presence. Van Riemsdijk¹⁸⁵ prepared a special indicator which he claimed could be used in the same manner as methylene blue.

A few of the methods especially useful in food bacteriology will now be presented:

A number of methods, many of which rest on the same principle, have been devised by growing an anaerobic organism in symbiosis with an aerobe; it is assumed that the aerobe uses up the free oxygen, thereby creating the desirable conditions necessary for the anaerobe. Hall¹⁷⁹ showed that methylene blue could not be used as a criterion of anaerobiosis in this case, because some organisms reduce the dye themselves and might give the technician false information. The presence of another organism, which removes the oxygen and gives off carbon dioxide, is an advantage as Rockwell¹⁸⁶ has shown. While other explanations have been offered to explain how the association functions in creating favorable conditions for the anaerobe, Novy¹⁸⁷ was satisfied that the removal of oxygen by the aerobe was the best explanation.

Torrey's Method. Torrey,¹⁸⁸ Zinsser,¹⁸⁹ and Beijerinck¹⁹⁰ suggested methods which were based on the cultivation of the anaerobe in the presence of an aerobe which absorbed the oxygen. A Petri dish about 10 cm. in diameter and two cm. high is poured with the medium which has been inoculated with the organism under study, or with the sterile medium if the plate is to be streaked. The plate is then placed in an incubator to dry, after which it is inverted into another dish at least 12 cm. in diameter, containing agar heavily inoculated with *Bacillus cereus*. The strictly aerobic *Bacillus cereus* will use the oxygen allowing the anaerobe to grow. Beijerinck used *Oidium lactis* instead of *Bacillus cereus*, because of its greater oxygen-consuming capacity.

Giltner's¹⁹¹ **H Tube Method.** This tube consists of two culture tubes fastened together to make an H. Pyrogallol may be placed in one arm and the culture in another. In place of alkaline pyrogallol an oxygen-consuming bacterium may be grown. Novy¹⁸⁷ reported that cultivation of *Bacillus subtilis* in one arm allowed an anaerobe to grow in the other. When H tubes are not available the culture tubes may be connected by means of glass tubing through one-hole rubber stoppers.

For the absorption of oxygen with chemicals alkaline pyrogallol, which has marked affinity for oxygen, is used. Many different contrivances have been devised for getting rid of oxygen in this manner.

Buchner's Method. In this method the culture tube is placed in a larger one, which contains the alkaline pyrogallol. It has the disadvantage that if some special support is not used to keep the culture tube above the surface of the pyrogallol, it is difficult to follow growth during incubation. These tubes may be prepared as follows:

Introduce two grams of pyrogallol into the bottom of a large test tube and place therein a support for the culture tube. This may be made from wood, cotton, glass, etc. After the culture tube has been placed on its support, introduce the sodium hydroxide by means of a pipette into the bottom of the tube, and seal the tube immediately with a rubber stopper.

Dimond¹⁹² modified the Buchner method in two ways. Bitting and Bitting¹⁹³ also suggested a modified Buchner method. The material was "plated out" in the bottom of an Erlenmeyer flask. The flask was then inverted in the absorbent.

Morse and Kopeloff's¹⁹⁴ **Method.** The main advantage of this method is that no special apparatus is required. Ordinary Petri dishes are used, and they may be sterilized in the usual manner. The procedure consists in taking two tops and two bottoms of ordinary Petri dishes and placing them edge to edge. They may be paired just before the medium is poured. The inoculated medium is poured into the bottom part, or sterile agar may be used and streaked with the inoculum later. After the medium has hardened and been inoculated, the dishes are turned over and five to 10 grams of dry pyrogallol acid are placed in the bottom dish to which are added 30 ml. of a five-per cent sodium hydroxide solution. A strip of surgeon's adhesive tape is then placed around the equator uniting the two halves. Morse and Kopeloff proved the integrity of their anaerobic culture dish with methylene blue.

Wright's Method. This is another absorption method and differs from the others only in method of procedure. It is especially adaptable to the isolation of anaerobic sporeforming bacteria. Decimal dilutions of the sample are introduced into sterile litmus milk. About one inch above the meniscus of the milk a tight cotton cylinder is forced, upon which are put about two grams of pyrogallol. This is treated with strong sodium hydroxide and the original plug replaced in the tube. This tube should then be heated for 15 minutes at 80°C. (176°F.) to kill all vegetative bacteria. Later incubation will give the characteristic changes. This method has several objections. It is difficult to remove the microorganisms which have grown without having some of the pyrogallol solution run down into the culture. Rockwell¹⁸⁶ reported that the use of pyrogallol acid was not entirely satisfactory since the carbon dioxide was entirely removed. Rockwell accordingly proposed charging the alkaline water with carbon dioxide before addition to the pyrogallol acid.

Other methods depending on about the same principles have been proposed by Zinsser,¹⁸⁹ Lentz,¹⁹⁵ Kuster,¹⁹⁶ and McLeod.¹⁹⁷

Varney's¹⁹⁸ **Method for Cultivating Anaerobes.** Varney proposed a method in which phosphorus was used for removing the oxygen in a tightly closed container. The apparatus consists of a standard museum jar into which is fitted a heavy wire frame to

hold the Petri dishes or tubes. Various sizes of museum jars may be used. When the jar is filled and the apparatus assembled ready for use, about one-half inch of water is placed in the bottom of the jar. The water absorbs the phosphorus pentoxide vapor formed by combustion of the phosphorus. To secure anaerobic conditions a piece of yellow stick phosphorus about one-eighth to one-quarter inch long is placed in the evaporating dish. This is a sufficient charge for the 5 x 12 inch jar. The asbestos disc is quickly placed over the dish and fitted snugly into it. The cover is then fastened on the jar and the phosphorus begins to burn promptly.

The air and oxygen may also be removed physically by a vacuum pump. In food-preservation factories where vacuum closing machines are available, the cultures may be hermetically sealed in a vacuum.

Boiling. Air is very soluble in water at room temperature. Winkler has found that one liter of water at 20°C. (68°F.) will dissolve about nine mg. of oxygen. By boiling water for some time, dissolved oxygen may be driven off. Special methods are then necessary to prevent reabsorption of air. In liquid media where heating will cause no change, this may be done by a layer of sterile vaseline or ligroin.

Novy's Method. The apparatus used in the application of this method consists of a large glass jar with a removable top, which has become known as the Novy jar. The culture may be grown away from oxygen by using an inert gas, vacuum, or alkaline pyrogallol. The jar is constructed with a glass stopcock, which will allow the removal of air with a vacuum pump. This may be combined with alkaline pyrogallol and give an atmosphere which is entirely free from oxygen.

The exclusion of oxygen mechanically is accomplished by a number of ingenious devices. Some of them are simple, while others are objectionable on account of the cost of apparatus or increased burden in the preparation room.

Dick's Method for Anaerobic Plates. Dick¹⁹⁹ suggested the use of paraffin for covering the inoculated agar in Petri dishes to make anaerobic conditions. The paraffin was sterilized and spread quickly over the surface while hot. One of the advantages of this method is that enumeration of the anaerobic bacteria is possible. The only disadvantage is the difficulty of seeing the colonies of the bacteria. Northrup²⁰⁰ proposed the addition of the dye Sudan III to the paraffin. This produces a color deep enough for distinguishing the white bacterial colonies. She finds it just as convenient to lift the paraffin cover from the surface of the agar when it is desirable to inoculate media, instead of cutting out a portion of it, as was suggested by Dick. This method is especially valuable for the isolation of anaerobic bacteria in pure culture where subsequent cultural and morphological examinations are desired.

Marino's²⁰¹ Method for Cultivating Anaerobic Bacteria as Modified by Krumwiede and Pratt. This method was used by Krumwiede and Pratt²⁰² for isolating fusiform bacilli. Two halves of a Petri dish are sterilized so that the bottom is placed in the inverted cover. The inoculated agar is then poured into the cover of the dish and the bottom of the dish laid on top of the agar, while it is still fluid. After the agar has solidified, the edges of the dish may be painted with paraffin to prevent the entrance of oxygen. According to Hall,²⁰³ unless this is done, there will be a progressive ingress of oxygen from the periphery inward, as indicated by the recoloration of methylene blue when that substance is used as a criterion of anaerobiosis. To prevent this, a seal of vaseline or paraffin had to be employed.

Liquid oils, such as paraffin oils, may be used in covering media to prevent the entrance of oxygen. It is generally supposed that these function mainly in a mechanical manner, but the statements of Larson²⁰³ and his colleagues seem to indicate that the oil functions by reducing the surface tension. Thompson²⁰⁴ has stated that solid paraffin gave better results than these liquid mineral oils. A greater percentage of

204. Thompson. 1920. *J. Infect. Diseases* 27, 240-244.

positive cultures were secured with solid paraffin than with liquid paraffin. This action was explained by the fact that solid paraffin prevents the downward diffusion of oxygen by convection currents. Gates and Olitsky²⁰⁶ also found that solid vaseline or paraffin gave more satisfactory anaerobiosis than the liquid mineral oils. These latter oils did not prevent the ingress of oxygen. The length of the column of liquid seemed to be of minor importance under a vaseline seal. Hall²⁰⁶ also reached the conclusion that solid paraffin or vaseline was a much better seal for anaerobic cultures. His statements were based on data secured with methylene blue as a criterion.

Beattie's²⁰⁷ Method. Ordinary test tubes containing plain or carbohydrate broths are used. Melted, sterilized vaseline is poured into the tube until a plug about one-half inch long is formed. The broth and vaseline are then boiled for 20 to 30 minutes, in order to expel any dissolved air, and allowed to cool. These tubes may be kept for an indefinite time and are airtight. When they are to be inoculated they may be melted in a water bath at 55°C. (131°F.). The sample may be introduced by means of a sterile pipette. The vaseline may then be heated over a flame to reform the solid plug, and the tube placed in the incubator. In order to remove any portion of the culture, a sterile sealed pipette (capillary) is thrust through the plug. This may be broken by forcing the end against the bottom of the tube, after which any portion of the culture may be removed. By melting the vaseline plug again the culture tube is sealed for further incubation. Kahn¹⁷¹ stated that the vaseline-boiling method was the most reliable for obtaining anaerobiosis especially in liquid media. He did not find the other methods involving the use of pyrogallic acid, vacuum exhaustion, platinized carbon, etc., reliable.

Brewer's Petri Dish Cover and Technic for Cultivation of Anaerobic Bacteria. Brewer devised a special cover to work in combination with a solid medium containing a reducing agent. It obviates use of anaerobic jars, petroleum seals, and chemicals other than those in the medium itself and makes possible surface cultivation. The medium which Brewer recommended is his sodium thioglycollate medium. Either a pour or streak plate may be made. After the agar medium has solidified, the Petri dish cover is replaced by the special "anaerobic lid" which is so designed that it touches the agar at the periphery and results in trapping a small amount of air over the surface of the agar. The reducing agent in the medium uses up this small amount of air, and an anaerobic condition is thus made. A glass rim on the lid forms a seal with the moist solidified agar; no other seal is required. One ml. of a 1-500 methylene blue solution may be added to each liter of agar to act as an indicator, the reduced center of the medium in the dish becoming colorless with an oxygenated periphery.

The Deep Agar Shake Culture. This is one of the older methods which has enjoyed wide usage down to the present day. It consists in distributing the material, from which it is hoped to isolate anaerobic bacteria, throughout melted cooled agar medium in a culture tube. The organisms develop colonies which may be seen by holding the culture tube against the light. Veillon²⁰⁸ adapted this method by preparing dilutions of the material to be analyzed. Three to six tubes of glucose agar were liquefied and cooled to 45°C. (113°F.) in a water bath. A small amount of the sample was placed in the first tube and carefully mixed. From this a series of dilutions was made in the other tubes. The medium was solidified and the tubes were incubated.

Miller, Garrett, and Prickett's²⁰⁹ Modified Deep Agar Shake Culture for Anaerobic Bacteria. This procedure is a modification of the older deep-tube methods of Roux²¹⁰ and Hall.²¹¹ Advent of the oval tube, the two broader sides of which are parallel, enabled Miller and his colleagues to develop a modified and more accurate deep agar shake culture for quantitative results. The ordinary oval tube was improved by providing it with a round neck and lip. The tubes are filled to the neck with medium, plugged, and

sterilized. Before use they are heated in a flowing steam sterilizer for 10 minutes. After cooling they are given decimal dilutions of the sample, and the medium is allowed to solidify. The necks are then filled with reduced methylene-blue agar containing 1/20,000 parts of dye and two per cent of dextrose at pH 8.2. This permits following the rate and depth of oxygen absorption.

Burri's²¹² Method for Isolating Obligate Anaerobic Bacteria. This was a deep-tube method, much like the agar-shake. The bottom of the tube was closed with a rubber stopper, which could be removed. The agar could then be forced out of the tube. The tubes, which were about the size of culture tubes, were plugged at both ends with cotton and sterilized in the hot-air oven. The rubber stoppers are sterilized under water in an autoclave. When the tubes are to be used, one of the cotton plugs is replaced with a rubber stopper. Three dilutions of the material under study in two per cent nutrient agar are layered into the tube and finally covered with a layer of sterile agar. After incubation, the agar plug may be pressed out into a sterile Petri dish. Hall,²¹³ who has given the anaerobic bacteria much study, stated that the Burri method is better than the so-called surface methods. He modified Burri's method as follows: The most suitable size of tube is 9 x 180 mm. The cork or rubber stoppers are placed in position before sterilization when they are used. Owing to the fact that they loosen during sterilization, Hall later found that Capes-Viscose caps could be placed over the stopper to hold it in place.

Greenberg's²¹⁴ Method for Single-Colony Isolation of Anaerobic Bacteria. This method was proposed as a reliable one for isolating anaerobic bacteria. It is based on a procedure for separation of single colonies of streptococci of Ward and Rudd.²¹⁵

Procedure: Using a one-mm. platinum loop, one loopful of an 18 to 24 hour broth culture is touched gently on the inside of the culture tube, so that only the barest film of culture remains on the loop. This inoculum is then transferred to a tube containing five ml. of sterile broth (type of broth is immaterial) and thoroughly mixed. The loop is flamed and a loopful of the inoculated broth is transferred to a tube of the semisolid medium, which has been heated in boiling water to displace oxygen and cooled to 45°C. (113°F.) immediately before use. The tube should then be rotated to distribute the organisms evenly. It is then placed in the incubator under ordinary aerobic conditions. The formula for the semisolid medium is given in the chapter on "Media."

The incubation period will vary with the organism under study. For *Clostridium welchii* the best incubation period was found to be overnight (16 to 18 hours) at 37°C. (98.6°F.). For all other anaerobes studied it was found best to leave the cultures at room temperature—approximately 22°C. (71.6°F.)—and place them in the 37°C. incubator the following morning. The development of colonies is then watched closely (up to 10 hours), the cultures being removed from the incubator when the colonies have reached a suitable size. Prolonged incubation at 37°C. may result in confluent growth, making it impossible to obtain single colonies.

In the case of mixtures of anaerobes and aerobes it has been found possible to eliminate the latter by (a) preliminary anaerobic cultivation of the mixture in fluid medium, and (b) by dilution of the resultant growth to the point where aerobic organisms are eliminated in the majority of tubes planted. The following procedure for dealing with contaminated material has been tried and has proved successful:

1. The product on test, or representative portion, is inoculated into 250 ml. of Brewer's thioglycollate medium (without dextrose) which has been previously heated in boiling water, and cooled to 45°C.

2. The inoculated flask is incubated anaerobically in a McIntosh and Fildes' jar for 24 hours at 37°C.

3. From this, at least 20 tubes, containing semisolid medium, are inoculated using the previously described method. These are incubated aerobically. Using the above technic and medium, separate colonies were successfully obtained from each of the

CHAPTER 3

YEASTS AND MOLDS

These fungi interest microbiologists in food preservation industries. They bring about both desirable changes and undesirable changes which cause spoilage in foods. Only those topics about organisms which have to do directly with food microbiology, are discussed below. Various fungi have made important places for themselves. The molds produce large amounts of useful enzymes which are used in food industries and medicine. Ramsbottom¹ has reviewed many of these applications. *Mucor rouxii* functions in the "amylo" process for changing starch to sugar. It does quite as well what malt has done. Certain *Penicillium* species have been used for a long time for ripening cheese. In some cases, as for certain fermented milks, mixtures of yeasts and molds are used. Yeasts are important not only in making alcoholic beverages but glycerol and fats.

RESISTANCE OF MOLDS AND OTHER FUNGI TO UNFAVORABLE CONDITIONS

Mold spores seem to be more resistant to certain unfavorable conditions than either yeasts or bacteria. Generally speaking, however, the bacteria are most resistant.

Concentrated Sugar Solutions. Grove² reported that a species of *Penicillium*, with which he worked, was inhibited by 65 per cent of sugar but showed scant growth even in 70 per cent solutions. Such concentrations cannot be tolerated by bacteria. Bezssonof³ also reported development of *Penicillium glaucum* in saturated sugar solutions while Kopeloff and Byall⁴ observed development of *Aspergillus sydowi*, *Aspergillus niger*, and *Penicillium expansum* in 60° Brix blackstrap molasses.

Heat. Mold spores are far less resistant to heat than bacterial spores. On account of their wide distribution in nature and the fact that heat is used to rid foodstuffs of objectionable microorganisms, heat resistance of mold spores had to be determined. According to Lode,⁵ dry heat at 125°C.(257°F.) killed mold spores in 15 minutes, but a temperature of 80°C.(176°F.) did not destroy them in seven hours. Thom and Ayers,⁶ however, found *Rhizopus nigricans* and *Oidium lactis* to be destroyed by pasteurization of milk at 54.5°C.(130.1°F.) in 30 minutes but that most strains of *Aspergillus* and *Penicillium* resisted this temperature to be killed only at 60°C.(140°F.) for 30 minutes. Streider and McClellan⁷ submerged flasks containing mold spores in a water bath at 20°C.(68°F.) and slowly raised the temperature to 100°C.(212°F.) to simulate as nearly

as possible conditions in bread baking. During this time of 35 minutes all mold spores were killed. Loaves of bread which had been exposed to molds were heated to 110°C.(230°F.) at 15-lb. pressure for 30 seconds and live steam for four minutes. The molds were not completely destroyed, but were markedly reduced in numbers. In the meat-packing industry Roderick⁸ found that molds in sausages were killed when they were heated in water at 60°C.(140°F.) for 10 minutes. Lewis and Yesair,⁹ using temperatures of 50°C.(122°F.), 55°C.(131°F.), and 60°C.(140°F.) exposed pure cultures of molds for periods of five minutes to one hour. None survived 60°C.(140°F.) for five minutes. Wallace and Tanner¹⁰ used a wider variety of species, reaching conclusions which, in general, agreed with those presented above.

An undescribed species of *Penicillium* was isolated by Williams, Cameron, and Williams¹¹ from blueberries and from soil of blueberry fields. Growth from ascospores occurred in a vacuum of 28.5 inches and from sclerotia in a vacuum of 26 inches. The destruction time at 82.2°C.(180°F.) was 9.7 minutes for ascospores and 1,000 minutes for sclerotia.

Ultraviolet Light. Use of this form of energy has been tried for controlling many different kinds of fungi. Whether it is successful depends on the fungus as well as the conditions under which it is used. It must penetrate to the fungus to destroy it. Mere irradiation of the food product will not necessarily destroy fungi in it. Meier and Crampoloff¹² were able to destroy cultures of *Cladosporium lycopersici*, *Botrytis cinera*, and *Penicillium glaucum* from tomatoes by 12, 10, and 40 minutes' exposure, respectively, to ultraviolet rays at a distance of 21 centimeters. In certain instances, however, even longer exposures did not destroy the cultures, probably because some spores were buried and accordingly not touched by the rays. Continuous irradiation was better than discontinuous. Meier and Crampoloff found that exposure of fresh fruit to ultraviolet light reduced rotting. Whether the process would be practical is difficult to infer from their results. Smith¹³ has reviewed much literature on this question. Mold spores on cardboard strips were not entirely killed in experiments by Tanner and Appling.¹⁴ On the underside of the strips which were not exposed many mold colonies developed, as would be expected. The conditions on the strips were not unlike those which would obtain on the surface of foods which were exposed to ultraviolet light. Sutton¹⁵ reported similar results. Molds were destroyed under some of the conditions which might exist in cheese factories. Sutton observed that dark-colored molds were much more resistant to exposure to ultraviolet light. Presence of pigment in the cells prevents penetration or absorption

of the energy. Spores of *Thamnidium elegans* and *Trichoderma lignorum* were spread on the surfaces of agar in Petri dishes and irradiated. Short exposures were found to appreciably reduce the load of spores and to check the growth of active mycelia present on the surface of foods. Exposure to the lamp for 40 minutes did not inhibit growth for more than two days. Thus it seems possible that short exposures to the lamp might appreciably reduce the load of spores and check growth of active mycelia on the surfaces of foods. Further work by Tomkins¹⁶ with such foods as oranges, eggs, and beef fat showed that while some destruction of these fungi resulted, the effect was not pronounced. Three types of lamps used by Schroeder¹⁷ on a mixture of several species of molds secured from a loaf of moldy bread, including *Aspergillus niger* and *Rhizopus nigricans*, were shown to differ considerably in killing molds. The lamps used were quartz 75-watt medium-pressure mercolite, QZ 15-watt low-pressure mercolite, and QZ 75-watt medium-pressure mercolite. The quartz lamp showed great killing power but was said to be too expensive and to give off too much ozone and short radiations to be used on foods. This lamp had the most energy in the 2537 Å region and shorter. The 15-watt QZ lamp, which was next in killing power, was second also in intensity of the 2537 Å line; and the QZ 75-watt arc was lowest in killing power on molds and had the weakest emission at 2537 Å.

Low Temperatures. Fungi are materially inhibited by low temperatures as are the bacteria. They cause some trouble, however, in foods in cold storage, such as meats and eggs. So-called "whiskers" and "black-spot" on such meats are caused by development of fungi which are discussed in several places in this book. Semeniuk and Ball¹⁸ identified many different fungi from meat from cold-storage lockers in Iowa. More information on this subject was published in 1940.¹⁹ Minimum temperature at which molds could develop was said to be clearly below 0°C.(32°F.). Even a temperature of -5°C.(23°F.) was said not to be a guarantee against development of molds; only a few developed at -8.3°C.(17.6°F.), while at -12.2°C.(10°F.) there was no development. Between this temperature and -17.8°C.(0°F.) no mold developed over a period of 27 months. Results of similar investigations have been reported by Panasenکو and Tatarenko.²⁰

Carbon Dioxide. This is not a very active inhibitory agent. Tomkins²¹ observed that storage of foods in concentrations up to 20 per cent encouraged rather than restricted growth of certain molds.

Direct Sunlight. Weinzirl²² reported that rather long exposure was necessary to harm mold spores, but they were killed. Viability of spores

in conidial material for 20 years was observed by McCrae.²³ This was in general confirmed by Becquerel.²⁴

Chemical Disinfectants. According to Lode²⁵ mold spores are killed by .2 per cent solutions of mercuric chloride, 5 per cent solutions of phenol, and 3 per cent of chloride of lime. More work could well be done in this field. It is known that boric acid is quite toxic to molds. Calcium and sodium salts of propionic acid have been found to inhibit molds in lower concentrations.

Tomkins²⁶ has shown that volatile substances, such as formaldehyde, ethyl alcohol, ether, and esters, exert a repressive action on the rate of growth of molds. When normally growing cultures were introduced into an atmosphere containing acetaldehyde, the growth was immediately changed. It was completely inhibited, inhibited for a short period after it was resumed, or was not materially affected, although it may have been slightly reduced. Such factors as temperature, concentration of acetaldehyde, and size of the colony determined into which of these three categories the behavior fell. It would take too much space to review all of Tomkin's conclusions. Volatile substances which retard and inhibit the growth of molds seem to fall into two broad groups, i.e., those which when present in definite concentrations retard growth irrespective of the age of the culture and time of exposure and those in whose presence there is a certain measure of adaptation with a consequent increase in the rate of growth ratio. This situation is somewhat complicated by numerous factors but in general the above statements reflect the conclusions which Tomkins reached.

In addition to the chemical substances just discussed, are the "mold inhibitors" or mycostatic salts much used in certain industries to control mold growth. Some of these are calcium or sodium propionate ("Mycoban") and sodium pentachlorophenate.

Tomkins' ²⁷ Method for Determining the Action of Volatile Substances on Fungi. The fungus is cultured in a liquid culture medium contained in a Petri dish. Ten ml. of the medium are placed in a dish about 9 cm. in diameter to form a shallow layer about 1.5 mm. in depth. To start growth a small sterile piece of porous material (flower pot) on which has been placed a drop of water suspension of spores is placed in the middle of the dish. Extreme care should be used not to move the dish. The fungus grows out from the porous material evenly in all directions in exactly the same way as when it grows on a nutrient medium solidified with agar. The diameter of the colony can be measured by arranging the dish on a piece of glass covering a sheet of squared paper. This method has advantages over a solid medium. The nutrient medium and the solution of the inhibitor may be sterilized slightly and mixed in the Petri dish in any desired proportion. Also, growth may be allowed to start in the absence of the inhibitor which can be added later, or the nutrient liquid may be removed by using pipettes and replaced by a fresh solution.

Production of Bactericidal Substances by Molds. Fleming²⁸ reported that a certain type of *Penicillium* produced a powerful bactericidal sub-

stance. The active agent was readily filterable and the name Penicillin was given to filtrates of broth cultures of the mold. It lost its power after 10 to 14 days at room temperature but could be preserved longer by neutralization. It was not destroyed by boiling for a few minutes; in alkaline solution, boiling for an hour markedly reduced its power. Autoclaving for 20 minutes at 115°C. (239°F.) practically destroyed it. While many bacteria are quite insensitive to it, pyogenic cocci are especially sensitive to it. White²⁹ found a strain of *Aspergillus flavus* which also produced bactericidal substances. Other strains had no such action. Since the application of this substance seems to be in other fields than microbiology of foods, it will not be discussed further.

Activity of Fungus Spores. Since spores are generally considered as resting stages in the life cycle of the fungus, some believe that they are entirely inactive. Such is not the case. They are living protoplasm and are, consequently, carrying on the functions of all living cells, although much more slowly. Effront³⁰ was able to demonstrate active enzymes in fungus spores. He reported that bacterial spores may be brought into such a state that while losing the essential properties of living cells they retain their ability to produce enzymes. Spores of *Bacillus subtilis* produced a large quantity of amylase and peptase. These conclusions were confirmed by Ruehle³¹ and Kopeloff and Kopeloff.³² Spores are, therefore, not to be considered as inactive agents. They are able to bring about changes in foodstuffs and other materials.

Effect of Moisture Concentration on Growth of Molds. Many foods, such as flour and cereals, keep as long as the moisture content is kept below a certain concentration. In an investigation of the flora of corn meal, Thom and Le Fevre³³ found that the moisture content greatly influenced development of both molds and bacteria. *Aspergillus repens* became an active agent in spoilage when the water content reached 13 per cent and above. At a moisture content of 16 per cent several other species of molds began to develop, while at 18 to 20 per cent, bacteria appeared. Quite similar conclusions were reached by Bailey and Thom.³⁴ The subject has also been studied by Tomkins³⁵ in connection with investigation conducted by the Food Investigation Board of Great Britain. The first work apparently considered only temperature and humidity. In this work, germination of *Alternaria citri* was observed in a relative humidity of 91 per cent, but not in 87 per cent.

The next report included the results of studies of the relation between temperature, humidity, and germination in the presence of nutrients. A drop of nutrient agar was placed on a slide and evaporated to dryness. Dry spores were then added and the slides placed in atmospheres with different relative humidities. Growth was found to be best at a temperature called

the optimum, which varied with the species. At this optimum temperature growth was possible over a wider range of humidities.

Tomkins observed that the surface on which the mold was placed had considerable to do with its ability to germinate.

RHIZOPUS

Rhizopus molds belong to the family of Mucoraceae. Great numbers of spores are borne in a sporangium. Hanzawa³⁶ grouped a number of *Rhizopus* species of industrial significance according to their morphological and physiological properties. Many different species have been described and it is probable that some of them are identical. Many descriptions are too incomplete and do not permit satisfactory comparison with an unknown species.

Rhizopus nigricans (*Mucor stolonifer*). This is a very common mold in certain types of foods. It seems to be widely disseminated in nature, having been isolated from soils in Europe and America by many investigators. *Rhizopus nigricans* was reported by Lloyd and Newell³⁷ and Stevens³⁸ to be important in rot of strawberries during shipment. Harter and Weimer³⁹ and Schneider-Orelli⁴⁰ gave the fungus wider significance in fruit spoilage. Storage of fruits at low temperature (below 1°C. [33.8°F.]) protects against spoilage by this mold.

Other species have been reported to play important roles in industrial processes and food spoilage. *Rhizopus delemar* was described by Hanzawa³⁶ and, on account of its very vigorous amylase, was said to be important in the manufacture of ethyl alcohol by the "amylo-process." *Rhizopus oligosporus*, *Rhizopus chinensis*, *Rhizopus tritici*, and *Rhizopus japonicus* are other species which are employed in fermentation where starch must be changed to fermentable sugars.

"Chinese Yeast." This is a "starter" used in China and other countries for preparation of an alcoholic drink from rice starch. It appears as little balls in which is a mixed flora of microorganisms, among which a few active ones have been singled out for intensive study. Calmette⁴¹ and Eijkmann⁴² described its manufacture. A mixture of husked rice mashed in cold water is treated with a number of drug preparations, among which garlic is usually found. A stiff paste is secured which is made into little balls. These are covered with straw in thin layers on mats placed in rooms heated to about 30°C. (86°F.). During this treatment the balls become covered with a velvety growth and assume the odor of yeast. Calmette stated that *Mucor rouxii* gained entrance to "Chinese yeast" from the rice husks and straw in which the small balls of rice are placed. Saito⁴³ isolated a species to which he gave the name *Rhizopus oligosporus* from rice flour used by the Chinese for making rice wine. Chrzaszca⁴⁴ reported another mold in Chinese yeast. He gave it the name

Mucor cambodja. A large number of different microorganisms were found in Korean koji, a kind of Chinese yeast, by Naganishi.⁴⁵ Korean koji was said to be more active than the Chinese product. Thirty-seven molds, nine yeasts, and four bacteria were isolated from 18 different koji preparations. Among the species studied were the following: *Absidia* sp., *Rhizopus* sp., *Willia anomala*, *Mycoderma* sp., *Bacillus subtilis*, and various members of the lactic acid-producing group of bacteria.

Yamazaki⁴⁶ observed that "Chinese Yeast Cakes," obtained in China and adjacent countries and used in the preparation of both fermented and distilled beverages, varied greatly in weight (.2-2,500 gm.), and also in size, color, and shape. The chief gross constituents were rice meal, other grains, vegetable drugs, and mineral matter in variable proportions. *Rhizopus*, yeasts, and *Mucor* were the organisms most commonly found; *Monascus*, *Penicillium*, *Monilia*, and *Aspergillus* were less frequent.

The Amylo-Process. This process has been used for many years in the Orient for fermenting grain mashes to alcohol. Molds are used in place of malt for hydrolyzing starch to fermentable sugars. In many cases the actual fungi which were involved were not known. *Aspergillus oryzae* was found to be one of the important species in use in Japan. *Amylomyces rouxii* is the name given to the fungus accomplishing the same ends in China. Owen⁴⁷ stated that the former fungus has never been successfully used in alcohol fermentation because it uses the alcohol toward the end of the fermentation; the latter fungus, however, is satisfactory both for saccharification of starch and fermentation of the sugar into alcohol. Owen stated that the amylo-process was developed by Calmette and Voldin in France and Belgium; since that time it has been used in many countries for fermenting starch to alcohol. While their first work was done with *Amylomyces rouxii*, Calmette later isolated and used *Rhizopus delemar* and several species of *Mucor*. Owen described the use of these fungi in the fermentation.

Among the various molds which have been found to be directly applicable in the amylo-process is *Rhizopus japonicus*, cells of which are especially rich in amylase. Ploberger⁴⁸ and Leopold and Buka⁴⁹ mentioned some of the factors which influence its activities. The former investigator mentioned other molds which are active destroyers of starch, *Aspergillus oryzae*, *Amylomyces delemar*, *Amylomyces rouxii*, and several *Aspergilli*.

MUCORS

In the same family with *Rhizopus* species are *Mucors*. The latter differ mainly in the fact that but one sporangiophore rises from the same place on the stolons. Some of the *Mucors* are important in industrial fermentations. A key to common *Mucors* was published by Jensen.⁵⁰ *Mucor*

mucedo, one of the first species studied by Brefeld,⁵¹ is widely distributed in nature and is probably the species usually encountered. It has been found in various foods. *Mucor cambodja*, described by Chrzaszca,⁴⁴ from rice cakes ("ragi") was reported to have much in common with *Rhizopus* species which are actively amylolytic. Wehmer⁵² described a species from the same source under the name of *Mucor javanicus*. According to Wai,⁵³ *Mucor sufu* functions in ripening of soybean cheese. *Mucor mucedo*, with a few other molds, is responsible for the white cotton-like growth, often called "whiskers," on foods which have been held in cold storage.

THAMNIDIUM

The members of this group resemble *Mucor* in many respects. They possess two kinds of sporangia. One is borne at the tip of a sporangio-phore and contains many spores while the other is borne on the hyphae and usually contains two spores. This fungus causes some trouble in meat coolers.

Low concentrations of carbon dioxide were found to be markedly inhibitory, by Moran *et al.*,⁵⁴ to development of *Thamnidium chaetocladioides* when growing on lean meat, and in artificial media at low temperatures.

Smith and Tomkins⁵⁵ described a case in which lean meat became brown and sticky, with an unpleasant taint, after hanging in a cold room. The cause was attributed to unusually heavy growth of *Thamnidium chaetocladioides*.

BOTRYTIS

This fungus is occasionally found by microbiologists on various organic materials. The characteristics of the group may be secured from the description of such a species as *Botrytis cinerea* as reported by Jensen.⁵⁰ Stevens and Hawkins,⁵⁶ when studying *Botrytis cinerea* spoilage of strawberries, reported that spread of the infection was favored by moisture and low temperatures which restricted the growth of other fungi. They found that the fungus grew on strawberries under very good refrigeration. The gray mold of hops was found to be *Botrytis cinerea* by Wormald and Cheal.⁵⁷ Bidault⁵⁸ found *Botrytis* species on frozen meats.

According to Smith,⁵⁹ phenol in a concentration of .4 per cent is fatal to spores of *Botrytis*.

DEMATIUM

This genus and its best known species, *Dematium pullulans*, has received much attention of mycologists and fermentologists. It is easily isolated from fruits such as grapes and may grow with appearances of typical yeast cells. *Dematium pullulans* forms a mycelium on which numerous conidia appear. It seems quite probable that conditions of

growth have much to do with appearance of these conidia. Klöcker and Schiönning⁶⁰ studied the fusion of cells for which this fungus is so well known. Two cells situated close to one another fuse, one cell seeming to penetrate the other. In the cell which is invaded by the other, elliptical cells appear, which may also bud. Such units are to be distinguished from ascospores. Weleminsky⁶¹ studied two cultures which were secured by exposing plates of wort gelatin in an orchard. One of these had quite a normal appearance, but the other varied considerably. The ability to form endogenous cells was retained in the later generations; these cells often separated and behaved perfectly similarly to the other free cells. The number of spore-bearing mycelial threads and the number of spores varied. One and the same thread often showed spores separated by normal forms at different places; the number of spores varied between two and eight. In order to find a cause for the variations, the author studied the effects of different conditions. Simple grape juice gave the best results. Varying the temperature and the nature of the light had no influence on the spore formation. Previous culture of the colonies on fruits and leaves and on gypsum blocks was also without effect on the spore-bearing capacities. The best method of inducing sporulation appeared to be to let the colonies dry and remain for one to three weeks, and then moisten them again with water. Weleminsky concluded that *Dematium pullulans*, de Bary, must be placed amongst Ascomycetes, and belongs to the simplest group, which comprises the Saccharomycetes and Exoascus organisms.

According to von Skerst,⁶² *Dematium pullulans*, under certain conditions, may cause ropiness in beer. Between 5°C. and 30°C. a yellow-white sediment forms on the bottom of the culture flask; later a characteristic film covers the surface of the liquid. Ropiness appears more readily in media poor in nutriment.

PENICILLIUM

This genus was established in 1809 by Link for all molds having a brush-like type of conidial fructification. The conidiophores branch at the apex and at the tip of each branch conidia are formed in chains. Several investigators have studied this important group of fungi. Results of one such study was reported by Thom,⁶³ whose report is illustrated with drawings which could be of great assistance to the food mycologist in determining unknown Penicillia. The Penicillia seem to be able to bring about desirable and undesirable changes in foods. Dox⁶⁴ studied the endoenzymes of *Penicillium camemberti* and reported the presence of erepsin, nuclease, lipase, emulsin, amylase, inulase, raffinase, sucrase, maltase, and lactase. Such an array of enzymes would seem to indicate a marked ability to decompose organic matter. While the green Penicillia cause spoilage in certain foods it should also be remembered that they bring about quite desirable changes as well. They act in certain cheeses

to bring out a characteristic flavor (Thom,⁶³ Stewart⁶⁵). *Penicillium camemberti* and *Penicillium roqueforti* have been used for ripening the cheeses which bear their names. Thom stated that *Penicillium roqueforti* has been described in dairy literature as *P. glaucum*. Dvorak⁶⁶ found that the mold formed a typical aroma without symbiotic development of another species as was suggested by Jensen.⁵⁰

In preparing mold powder to be used as a starter for blue-veined cheeses Hussong and Hammer⁶⁷ grew the mold on bread under aseptic conditions, dried it, and ground it to a fine powder. The advantages of this procedure are a powder rich in mold spores, short time for preparation of the starter, and freedom of the powder from contamination.

Penicillium brevicaulle is another cosmopolitan species which has been put to practical use. It has been utilized in a technic for detecting the presence of arsenical compounds in various materials. *Penicillium crustaceum* is found on decaying wood, bread, etc. It grows on bread at temperatures between 10°C.(50°F.) and 25°C.(77°F.). It gives an abundant even growth, white in the beginning, turning to a dark brown. Bidault⁶⁸ found the fungus on frozen meat. Other species have been found in cheese and other dairy products.

Biological Test for Arsenic (Schneider⁶⁸). Tests for arsenic are usually carried out by the different chemical methods. In foreign countries, however, a biological test with *Penicillium brevicaulle* is used. This mold, when grown on a medium containing arsenic, gives off garlic-like odors. Gosio⁶⁹ first observed this and found seven different molds which formed this garlic-like odor from foods containing small amounts of arsenic. Crumbs of bread (wheat) form the best culture medium for this mold and the incubation is done at a temperature of from 28 to 32°C.(82.4 to 98.6°F.). In the presence of not more than .00001 gram of arsenic in such culture, there will be noticeable a distinct and very characteristic garlic odor which may persist for months if the culture is not killed. These molds do not produce garlic odors with sulfur, phosphorus, antimony, boron, and bismuth compounds, but they do have the power of converting selenium and tellurium compounds into volatile substances having the garlic-like odor. The following is the procedure for making the test:

Procedure: If the material to be examined is liquid, let the dry bread crumbs (either white or graham) absorb it to saturation, then scatter a small quantity of fine crumbs over the surface. If the material to be tested is solid, grind or cut and mix with an equal amount of bread crumbs and then moisten with a little sterile distilled water. Place the prepared material in a sterile flask of suitable size and plug with sterile cotton. Sterilize the flask and contents by the usual fractional method at 100°C.(212°F.) or for 30 minutes in the autoclave. Absolute sterilization must be secured. There is no danger of volatilizing the arsenic at these temperatures. As soon as the flask and contents are cold, inoculate with the mold, as follows: The mold cultures may be grown on bread or pieces of potato. Remove a small quantity of the

69. Gosio. 1892. Riv. Ig. e Sanit. Pub. 9, 201-230; 261-273.

mold in the spore forming stage and mix with peptone salt solution or sterilized water. Add enough of the mold suspension to moisten the bread in the flask. Do not add more of the spore-bearing material than the mass (bread and arsenical substance) in the flask will absorb, as too much moisture will retard the growth of the fungus. Cover the inoculated flask with a rubber cap and incubate at a temperature of 37°C. (98.6°F.), although the ordinary room temperature will answer the purpose. As soon as the growth is clearly visible to the naked eye, which may be within 24 hours, the characteristic garlic odor will be noticeable on opening the flask. If no odor is apparent, again seal and incubate for 24 hours or longer. In case the substances to be tested are strongly acid, they may be first neutralized by means of calcium carbonate. It must be kept in mind that *Penicillium brevicaulle* as well as other molds, will convert tellurium and selenium salts into volatile substances having a garlic-like odor. The arsenic and selenium odors are closely similar, but that from selenium is somewhat different in quality, more like that of mercaptan. The test is extremely delicate, .00001 gram of arsenic can be recognized with a certainty. A solution of .00001 gram of potassium tellurite in 10 ml. of mold-infested gelatin medium, in a cotton-plugged test tube, gave a strong odor of garlic for several weeks.

Another statement of procedure was prepared by Smith and Cameron.⁷⁰ Bisbini⁷¹ reported that the most sensitive fungus for detecting arsenic is *Penicillium brevicaulle*. He was able to find two other fungi in the air which had the same ability. Husz⁷² tested potato cultures of 90 different molds respecting their action on various compounds and preparations containing arsenic. The following organisms were found to produce free arsine: Two forms of *Penicillium brevicaulle* and an organism probably closely related, and possessing a chocolate brown color; *Aspergillus candidus*, *A. clavatus*, and three other *Aspergillus* forms (*A. D.* and *T.*) not identified, two of which were found on oil paint on the walls of a damp room; finally, an *Actinomyces* form found on the same paint and apparently very widely distributed. The last-mentioned organism, when grown in lactose, or maltose-agar cultures, forms colonies, which after a time appear as if covered with a white chalky powder; this is due to the formation of spores.

According to Tiego,⁷³ fungi, such as *Penicillium brevicaulle*, *Aspergillus glaucus*, *A. virescens*, and *A. niger*, *Mucor mucedo*, and *M. ramosus*, have the ability to decompose arsenic compounds, with formation of diethylarsine, which has a very characteristic odor. This makes possible the detection of .001 mg. of arsenic. Similar reactions are obtained with selenium and tellurium compounds.

CITROMYCES

The members of this group are especially well known on account of their marked ability to form acids. Citromyces are quite closely related to *Penicillium*. They differ, however, by possessing a simpler structure with less branching. Wehmer described two species, *Citromyces Pfefferianus* and *Citromyces glaber* as important in transforming sugar into citric acid. Wehmer⁷⁴ and Schreyer⁷⁵ stated that a species of *Aspergillus niger*

converted calcium gluconate into citric acid and smaller quantities of oxalic acid; oxalic acid was said to be produced almost exclusively by *Aspergillus niger cinnamomeus*. The mechanism of citric acid fermentation was unexplained. Fernbach *et al.*⁷⁶ received a British patent for making citric acid with *Aspergillus* species. This fungus is inoculated into a solution of salts and dextrose with sufficient hydrochloric acid to give an acid medium. Other organisms are kept out in this manner. A yield of citric acid amounting to 65 per cent of the sugar is secured. The residual sugar is fermented with yeast and the alcohol and carbon dioxide boiled off. Martin⁷⁷ secured a yield of citric acid amounting to 50 per cent of the sugar. Currie⁷⁸ secured the formation of large amounts of citric acid from sugars by the action of *Aspergillus* species. Currie used a mineral-salt-sugar medium. The average yield was about 11 per cent of citric acid. Other species of molds which produce citric acid from sugars have been described by Butkewitsch.

ASPERGILLUS

The members of this group are widely disseminated in nature. The conidia are borne on a fruiting organ called a basidium. The immediate structures which support them are sterigmata. The most recent reliable discussion of the group is by Thom and Church.⁷⁹ This book contains keys, discussions of nomenclature, and descriptions of species. The *Aspergillus glaucus* group has been studied by Thom and Raper.⁸⁰

SACHSIA

Sachsia albicans, discovered by Bay,⁸¹ was one of the first species in the genus to be reported. Later, Lindner added the species, *Sachsia suaveolens*, said to produce a desirable odor in certain fermentation products.

FUSARIUM

Fusarium species have been connected with the spoilage of various foodstuffs. While vegetables have been attacked especially, members of this genus have also been isolated as the cause of spoilage of cheese. Loubiere⁸² isolated *Fusarium sarcochroum* on a brick cheese; Laxa⁸³ isolated a *Fusarium* species from a cheese which was covered with a reddish, slimy layer. The same difficulties and confusion so often encountered in the study of other groups of fungi are encountered in the study of *Fusaria*.

So much uncertainty existed, however, over identification and taxonomic relationships that a conference of specialists was held in August, 1924, at Madison, Wisconsin. At this conference cultures were compared and information collected which has given a firmer basis for future progress. The first problem which the conference had to settle were the criteria

of the norm. A complete discussion has been published by Sherbakoff⁸⁴ and Wollenweber.⁸⁵ The criteria of the norm were tabulated under the headings: normal reproductive states, color characteristics, minor characters, and abnormal characters. This characterization cannot be reproduced here. They should be consulted by food bacteriologists since *Fusaria* may be encountered in many foods.

CLADOSPORIUM (HORMODENDRON)

Members of this genus have been isolated from various foods. *Cladosporium herbarum* is probably identical with *Hormodendron cladosporoides*. Such is the opinion of Brooks and Hansford,⁸⁶ who published an investigation of the fungi on cold-storage meat. They also discussed at considerable length the relation of *Cladosporium* to *Hormodendron*. Brooks and Hansford could not confirm the observations of Bancroft⁸⁷ that conidia of the *Hormodendron* type were formed by *Cladosporium* at a temperature of 15.5°C. (60°F.) or above, while below 13.5°C. (56°F.) conidia of the same type were secured. The *Hormodendron* type of conidia was secured in every culture grown at low as well as at high temperatures, both on solid and liquid media. In nature the *Hormodendron* type was less common than the *Cladosporium* type. Brooks and Hansford believed that *Cladosporium epiphyllum* and *Cladosporium aphidis* must be considered as synonyms of *Cladosporium herbarum*.

Hormodendron cladosporoides. This fungus, which resembles some of the common molds, is commonly present in certain foodstuffs. It has been recently characterized by Jensen⁵⁰ and by Brooks and Hansford.⁸⁶ The latter investigators carried out a complete investigation on strains which were isolated from frozen meat and on strains from pure culture collections. On account of its length, the excellent characterization of this species by Brooks and Hansford cannot be reproduced here. The species is of special interest on account of its ability to grow below the freezing point. This ability gives the species its significance in "black spot" on frozen meat. Temporary freezing at -6°C. (21.2°F.), according to Brooks and Hansford, did not injure the organism, but prolonged freezing up to a month at -6°C. eventually killed the spores of most strains, except those which could grow and germinate at this temperature.

SPOROTRICHUM

The best known species of this genus is *Sporotrichum carnis*. It has been completely characterized by Brooks and Hansford. This species is capable of growing just below zero and gives rise to the white woolly patches on frozen beef. It grows very slightly, if at all, at -6°C. Brooks and Hansford believed that the strains isolated from meat belonged to one species.

85. Wollenweber. 1914. J. Agr. Res., 2, 251-285.

86. Brooks and Hansford. 1923. Food Invest. Bd., Spec. Rept. 17.

87. Bancroft. 1910. Ann. Bot. 24, 359.

Haines⁸⁸ found that the optimum temperature for growth of *Sporotrichum carnis* on Czapek's agar medium was 25°C. (77°F.). Growth can occur at 30°C. (86°F.) but is restricted. Fairly good growth occurred at -5°C. (23°F.) on supercooled agar; growth also occurred at -7°C. (19.4°F.). In no case was growth observed on frozen agar up to two months.

WARDOMYCES

This genus of the Dematiaceae was made by Brooks and Hansford⁸⁶ for a fungus isolated from a consignment of skinned Australian rabbits. The genus was named in honor of Professor Marshall Ward, the British botanist. Brooks and Hansford stated the characteristics of the genus as follows:

Wardomyces anomala on the rabbit flesh was almost indistinguishable from *Sporotrichum carnis*. When isolated, however, it showed quite different characteristics. The spores germinate to form a branched mycelium of hyaline hyphae 2-4 μ wide. The conidiophores rise as short lateral branches, 15 to 25 μ long from the vegetative hyphae; they remain hyaline and become septate with age. Some conidiophores are unbranched and form rarely short chains of two or three conidia, the distal conidium being the oldest; others branch repeatedly and form heads of spores which usually arise separately, although under certain cultural conditions two spores are formed occasionally in a chain. Two or three spores are often produced on each of the terminal cells of the branches conidiophore, one spore being formed terminally and the others in succession laterally.

ALTERNARIA

These fungi are characterized by muriform conidia which are in chains. Conidiophores are erect.

CLAVICEPS

One of the best known members of this group is *Claviceps purpurea*. This species attacks rye and the sclerotium constitutes ergot. Ergot is a vasomotor stimulant and causes contraction of the involuntary muscles. Ergotized grain has caused a number of very serious outbreaks of poisoning when such grain is made into flour.

OIDIUM

These fungi lack well-defined fruiting bodies. Each mycelial thread seems to be able to break up into reproductive units called oidia. The shape of the oidia is quite characteristic and, once it has been learned, serves to aid in identification of the species.

Oidium lactis. This mold often referred to as the sour milk mold will develop on sour milk as a dull white, velvety layer. The greater part of the mycelium is submerged beneath the surface of the medium. It is especially characterized by dichotomous branching as shown in the illustrations in many publications. It has been encountered in a number of industries and plays an important role in the making of certain kinds of cheese. Jensen reported it in the soil. *Oidium lactis* has caused some large losses in the dairy industry. In Tasmania, this fungus is regarded as one of the main causes in the spoilage of butter. It seems that the fungus will grow in butter when the water content is sufficient and when the temperature is not too low. The presence of this mold in butter was also observed by Thom and Shaw.⁸⁹ In margarine it seems that

88. Haines. 1931. J. Expt. Biol. 8, 379-388.

89. Thom and Shaw. 1915. J. Agr. Res. 3, 301-310.

Odium lactis does not cause rancidity (Jacobson⁹⁰). *Odium lactis* is widely disseminated in nature and has appeared in many foods.

Other oidia, such as *Oidium caseovarians* of Burri and Straub⁹¹ and *Oidium rubrum* of Proks,⁹² have been isolated from cheese. Smith⁹³ reported that the sour rot of lemons in California was due to *Oidium citri*. Artificial inoculation of the fungus into sound fruit reproduced the spoilage in 48 hours.

Not many investigations have been carried out on *Oospora lactis*. Gibson⁹⁴ studied 61 cultures isolated from butter. The temperature optimum for growth was between 20°C.(68°F.) and 28°C.(82.4°F.) with abnormal or restricted growth at 10°C.(50°F.) and 30°C.(86°F.) except in two cultures where the optimum was 30°C.(86°F.). Three cultures resisted 57.2°C.(135°F.) for 30 minutes, one survived 60°C.(140°F.) for 30 minutes. However, none of them resisted 62.8°C.(145°F.) for 30 minutes. A salt concentration of 7.5 per cent interfered with growth while only five showed any sign of growth at 10 per cent of salt. Tanner and Hofer⁹⁵ also sought information on heat resistance of *Oospora lactis*. Two hundred and twenty-four cultures were isolated from samples of cream from a wide geographical area; none was able to resist pasteurization in cream at 62.8°C. for 30 minutes; 144 cultures were exposed in cream to 57.2°C. for 30 minutes; eight resisted this temperature. Pasteurization at 51.7°C. (125° F.) did not kill any of the cultures used in this investigation. Temperatures ranging from 125 to 145°F. at 5°F. intervals were used to determine thermal resistance of nine cultures in phosphate solution; one fairly heat-resistant strain withstood pasteurization for 30 minutes at all temperatures used up to 20 minutes at 145°F.

MARGINOMYCES

This is a relatively new genus, proposed by Laxa⁹⁶ for a mold which caused black spots in margarine. The fungus was believed to be a new species to which the name *Marginomyces bubaki* was given. The mold grew in margarine as a thread-like net-work, green at first, but later becoming black. Long threads and conidia were produced. As is the case with most molds, the species is not very heat resistant. It was killed in five minutes at temperatures between 60°C.(140°F.) and 70°C.(158°F.). One minute at 100°C.(212°F.) killed it. The fungus was sensitive to boric acid, a preservative prohibited in foods in many countries. It was somewhat resistant to sodium benzoate. On account of this fact, Laxa stated that control of the fungus is dependent on the use of sterilization and control of such factors as water supply, etc.

ACTINOMYCES

Actinomycetes are filamentous, mold-like organisms quite widely distributed in soil and may, consequently, be expected in certain foodstuffs.

Buchanan⁹⁷ and Breed and Conn⁹⁸ have discussed the nomenclature and classification of Actinomycetes. The soil species have been studied especially by Waksman⁹⁹ in America. Conn stated that nearly 40 per cent of the soil microorganisms that develop on laboratory media are Actinomycetes. There is little doubt but what some bacteriologists unfamiliar with the characteristics of organisms in this group are confusing them with bacteria.

Mycelial Formation. The members of this family form a complex mycelium, much as do the molds. It is branched and may be submerged in the medium or develop on the surface with aerial hyphae. The hyphae from the aerial mycelium may "break up" into shorter or longer particles. According to Orskov¹⁰⁰ this disintegration has nothing to do with the reproduction of the fungus. The aerial hyphae may be straight or they may be bent and curled. During growth the aerial mycelium may be seen to develop peculiar globules at the tips or on the sides of the hyphae. These are liquid in nature and appear more abundantly when the fungus is growing best.

Spore Formation by Actinomycetes. Orskov¹⁰⁰ described the formation and appearance of spores somewhat as follows: After a lapse of time, the hyphae in certain places become irregular in outline so that the threads beginning from the tips display a series of baggings and constrictions; one might be tempted to compare the picture to a string of sausages, the constriction between the sausages being but slightly pronounced. Tracing this irregular thick portion of the hypha downwards from the tip, it will be seen that it passes into a regular, somewhat thinner, filament. The irregular portions of the filaments begin almost simultaneously from the tips downward to divide into a series of equal-size parts of oval or spherical shapes, lying quite closely to one another. The spores are not separated from one another by septa; sporulation occurs by division of the protoplasm into almost equal-size parts, without the walls of the hyphae having any part in the process. Thus the individual spores are separated from one another by "empty" spaces.

Actinomyces were found by Haines¹⁰¹ in all stores examined where meat was being held. They were found in scrapings from the walls and in straw and other debris on the floor. Haines believed that these organisms which contribute so greatly to abnormal flavor of meats may be brought into meat-preservation establishments on such material. Haines thought that these organisms were probably responsible for off-flavors and odors of cold-stored meats. Actinomyces in culture gave rise to peculiarly characteristic musty odors. Stored foodstuffs, particularly fats and eggs, were said to be extraordinarily sensitive to the presence of such odors. Results of experiments were reported during which fats were stored in a

glass jar above, but distant from, cultures of actinomyces. After two weeks' storage at $-5^{\circ}\text{C}.$ ($23^{\circ}\text{F}.$) observers stated that the exposed fat had an odor which was generally characterized as "musty." After cooking, however, this taste could not be detected. After three months' storage, however, cooking for one hour did not dissipate the odor. Haines¹⁰² observed that measurements of the rate of growth of actinomyces from cold-stored food show that the majority of the strains studied have their optimum temperature at $37^{\circ}\text{C}.$ ($98.6^{\circ}\text{F}.$). They are capable of growth from 40 to $5^{\circ}\text{C}.$ (104 to $41^{\circ}\text{F}.$), growth becoming infinitely slow at just above $0^{\circ}\text{C}.$ ($32^{\circ}\text{F}.$). One strain, however, had its optimum temperature for growth less sharply defined at 20 to $30^{\circ}\text{C}.$ (68 to $86^{\circ}\text{F}.$) and grew well, though slowly, at $0^{\circ}\text{C}.$ The curve obtained by plotting the "velocity constant of growth" against temperature suggests that growth becomes infinitely slow at about $-5^{\circ}\text{C}.$ ($23^{\circ}\text{F}.$).

An actinomyces-like fungus was isolated by Sartory and Meyer¹⁰³ from swollen cans of preserved foods. It was much like *Actinomyces thermophilus*, Gilbert, but certain characteristics seemed to place it among the Mycobacteriaceae in the genus *Corynebacterium*. The fungus was apparently quite thermophilic in nature. Unfortunately the authors gave no information on its heat resistance.

Certain species of Actinomyces have been found recently to produce bactericidal substances. Whether they might be significant in the food-preservation industry is not known.

ENDOMYCES

The organisms in this family, like those in Monilia, are between the true yeasts and molds. Zender¹⁰⁴ has characterized the family Endomycetaceae and included three genera, *Williopsis*, *Schwanniomyces*, and *Endomyces*. Several species are commonly encountered. Lindner described *Endomyces fibuliger* from bread on which it formed white chalky spots. *Endomyces mali* was isolated for the first time by Lewis.¹⁰⁵ Rose,¹⁰⁶ however, believed that it was identical with *Endomyces fibuliger*.

Nadson and Konokotina¹⁰⁷ were members of a commission appointed in Russia in 1917 to investigate the utilization of yeasts for the supply of foodstuffs, of which the war had brought about an acute shortage. Attention was first drawn by Lindner to the possibility of cultivating certain yeasts for the production of fat. Various fat-producing molds occur in the sap which exudes from birch trees in the spring, and from this source *Endomyces vernalis* was isolated, previously described by Ludwig and by Lindner.

The fat produced by *Endomyces vernalis* is liquid, yellowish in color, and resembling olive oil in appearance and flavor. The chief constituent is triolein, but there are also present free fatty acids. On heating for sev-

eral hours at 100°C.(212°F.), a loss of weight occurs which may amount to as much as 30 to 40 per cent owing to decomposition and escape of volatile acids.

Fat yeasts, after drying or boiling, are palatable and perfectly wholesome. Potato cultures, mixed with flour and some sugar, have been eaten with relish.

BYSSOCHLAMYS

This genus has become of interest to food technologists on account of the fact that one member, *Byssochlamys fulva*, disintegrates the tissues of processed fruit. The genus was proposed by Westling¹⁰⁸ and Olliver and Smith¹¹⁰ described *Byssochlamys fulva*. This fungus is readily cultivated on laboratory culture media. It is present on ripening fruits in the fields and orchards and is probably associated with the soil. The ascospores were reported by Olliver and Rendle¹⁰⁹ to be able to resist a temperature of 86 to 88°C.(186.8 to 190.4°F.) for 30 minutes in many fruit sirups. Ability to develop under reduced oxygen pressures makes it possible for the organism to develop in canned fruits after it has survived the process. Olliver and Rendle¹⁰⁹ reported the fungus could be cultivated on a potato-extract agar made from a base solution of inorganic salts containing 10 per cent of sucrose. Details of morphology and physiology will not be presented here. Reference may be made to the paper by Olliver and Smith.¹¹⁰ Results of heat-resistance studies on its spores have been reported in the chapter on "Canning."

SPORENDONEMA

A member of this genus, *Sporendonema epizoum*, has been found to be the cause of discoloration of salt fish by Frank and Hess¹¹¹ who stated that Ciferri and Redaelli¹¹² grouped all of the brown molds, heretofore placed in several genera, into one genus, *Sporendonema*. Reasons for doing this were morphological and cultural. Frank and Hess studied 26 cultures. They believed that *Torula minuta* of Hoyer should also be placed in this genus.

MONILIA

Monilia are fungi which possess characteristics of both yeasts and molds. *Monilia candida* is, perhaps, the best known saprophytic species. Discovered by Bonarden, it was completely characterized by Hansen, who found it in fresh dung and fruits. A very active fermenting species is *Monilia vini* of Osterwalder.¹¹³ It is of special interest because it ferments cane sugar without secretion of invertase. *Monilia variabilis*, isolated by Lindner¹¹⁴ from white bread, is quite pleomorphic. The mycelium and conidia of *Monilia sitophila* impart to "Outjorm," an edible cake made

114. Lindner. 1898. Wchnschr. Brau. No. 16.

in Java from ground nuts, an orange color. Went ¹¹⁵ found that ordinary simple substances supported growth of the fungus.

Black spots on cheese rinds have been found by Burri and Staub ¹¹⁶ to be *Monilia niger*. Further data were published by Maurizio and Staub.¹¹⁷ Two species, *Monilia nigra* and *Monilia fusca*, described by Browne,¹¹⁸ were said to be destructive organisms in raw cane sugar.

Henneberg and Kniefall ¹¹⁹ reported a case where *Monilia sitophila* infected and grew in a dairy plant.

Pathogenicity of Molds in Foodstuffs. There is very little evidence that moldy food causes illness. Church and Buckley ¹²⁰ fed common saprophytic species to laboratory animals without ill effects. Dinwiddie ¹²¹ reported similar observations after feeding a colt pure cultures of *Penicillium glaucum*. Gortner and Blakeslee ¹²² and Bodin and Gautier ¹²³ reported the formation of toxin by *Rhizopus nigricans* and *Aspergillus fumigatus*. Too little is known about such toxins to know whether they would be of significance.

Himmel's ¹²⁴ Method for Studying Mold Mycelium. In order to avoid the unsatisfactory method of studying mold hyphae which is now commonly used, Himmel proposed the following:

Between two glass slides (5 cm. by 11½ cm.) are placed layers of filter paper of the same size as the glass slides, the interior portions of which have been cut so as to form a border of filter paper about 1 cm. wide. A small piece (2 or 3 cu. mm.) of the moist bread on which the culture is growing is placed between the glass slides in the center of the band of filter paper. The slides are then tied together with thread, the filter paper moistened by dipping the edges of the slides in water, and the whole mount placed under a bell jar. In about two or three days the stolonifers will extend outward in various directions from the moist bread, and wherever they come in contact with the glass surface rhizoid-like hyphae and sporangiophores are produced. This may now be studied either with the compound microscope or with the binocular microscope.

This enables the student to trace the stolonifers with ease from their origin to their attachments to the glass and to study the sporangiophores and rhizoid-like hyphae in their natural positions without any disturbance of the hyphae or any danger of their drying during the study.

Coupin's ¹²⁵ Method of Preparing Permanent Preparation of Molds. Hanging drop preparations of molds may be made by suspending them in a drop of alcohol (50 to 95 per cent) and then adding after the alcohol has about one-half evaporated, a drop of a solution prepared as follows: .8 per cent of mercuric chloride (aqueous); gum arabic, 30 grams; glucose, 10 grams. Coupin was able to prepare permanent preparation of some of the common molds.

Detection of Molds in Foods. That this group of fungi has been closely related to food spoilage is quite apparent, but it remained for Viehovever ¹²⁶

126. Viehovever. 1917. J. Amer. Pharm. Assoc. 6, 518-524.

to suggest a laboratory method which could be used for detecting their presence.

Cultural Method. Specimens of the suspected food may be inoculated onto solid media and incubated to allow germination of the mold spores or vegetation of the hyphae. This method is applicable to only those foods which contain living molds or spores. It could not be applied to foods which have been prepared for a long period. It might take several days for the molds to grow.

Microscope Examination Without Special Treatment. This involves what is ordinarily called direct examination. A portion of the material is examined in a hanging drop or between a cover glass and slide. With this method the detection of molds rests on the absence of extreme decomposition processes. Howard's method for the control of tomato products is an example of the use of this method in practice.

Microscope Examination After Special Treatment. Viehovever¹²⁶ has proposed a test which is based on the fact that certain fungi possess a substance chemically different from cellulose in their cell walls. A large number of investigations has shown this substance to be chitin, a compound of complex structure. Viehovever (1912) also demonstrated the presence of chitin in the walls of certain fungi. Using this information Viehovever proposed the use of this substance as an index of the presence of mold or ergot in foods and flour. According to Viehovever, the material should be heated to almost boiling with 40 or 50 per cent KOH or NaOH for 40 to 60 minutes. After centrifuging if necessary, the excess alkali should be decanted and possibly pressed out with a glass rod. The material should then be washed with alcohol or glycerol and perhaps even neutralized with acid. The mixture is then treated with iodine-potassium iodide solution (two parts of iodine and one part of potassium iodide in 200 parts water). The excess iodine is then replaced by dilute sulfuric acid (1%). Chitin is indicated by a red or violet color.

Mol's¹²⁷ Method for Estimating Molds in Foods. Emmerling first proposed this method which Mol modified. Emmerling's method consisted of mixing five grams of the substance to be examined with a definite amount of sterile water, preferably in a sterile Petri dish. This mixture was then allowed to incubate at 37°C. (98.6°F.) for several days. The interpretation of results depends on the amount of surface covered. In view of various objections to this method, Mol modified it by studying growth on a solid medium. For this purpose a plum infusion-agar medium was prepared. Two hundred grams of plums were soaked in 500 ml. of water, heated, and filtered several times. Later, sterile agar solution was added.

One gram of the material to be tested is ground in a sterile mortar with 10 ml. of sterile water until a homogeneous suspension is secured. One ml. of this suspension is placed in a sterile Petri dish to which are added 10 ml. of the sterile plum agar. The plates are incubated for three days at 25°C. (77°F.) and the colonies counted. At the end of this time they are usually small enough to count.

Determination of Smut Spores in Flour and Cereals (Bredemann¹²⁸). Grind from three to five grams of flour to pass through a .3-mm. square mesh and dry. Clear with 10 parts of chloral hydrate in five parts of water to which are added five parts of glycerol and three parts of 25 per cent hydrochloric acid. A preliminary test is made by adding a few drops of the clearing solution to a small amount of the sample on a slide; this is covered and boiled and examined. If there are fewer than five spores per field with a magnification of 150, the main samples may be used. If there are more than this number dilute one part of the sample with nine parts of rice starch and thoroughly

127. Mol. 1937. Ztschr. Untersuch. Lebensm. 74, 189-191.

128. Bredemann. 1912. Landw. Vers. Stat. 75, 134-157.

grind in a mortar. Five to eight milligrams of the flour are weighed onto a slide and rubbed up with a suitable amount of the clearing solution after which it is heated over a small burner but not boiled. The preparation is then covered with a 20-mm. cover glass and heated slowly to boiling to remove air bubbles and clear the preparation. Then count the smut spores with a magnification of 165. The number is calculated for 10 grams and this divided by 450,000 for the milligram *Tilletia* spores in 10 milligrams. Ten times this is the per cent smut present.

Determination of Rust Spores in Cereals (Groh¹²⁹). Groh proposed two methods for determining rust spores in bran.

First Method. Ten grams of the sample are shaken in water in a 100-ml. flask which is diluted to the mark. The contents is then poured into a beaker. A drop of this is then taken by means of a stirring rod and placed on a counting cell of such size that the number of counts made by the microscope corresponds to the number of millions of spores in 10 grams. Groh found on an average 1,002 million rust spores in a gram.

Second Method. The bran is shaken up in water and then thrown onto a sieve and the liquor collected. Several washings are made until the liquor reaches 175 ml. in quantity. Then 20 ml. of zinc chloride solution are added and the liquor made up to the mark. Fifty ml. are centrifuged and the precipitate of spores and other material is treated with H_2SO_4 so that the volume is about five ml. The spore count is then made on this liquid by means of the hemocytometer as shown in the first method above.

Control of Molds. Development of molds in factories causes considerable loss. Some factories have had to resort to expensive air-conditioning systems in attempts to control these fungi. These have done much but have not entirely eliminated mold spores in all cases. Some food preparation plants are kept under air pressure to prevent ingress of mold spores in air. Germicidal paints are also used. A new departure in this effort is use of ultraviolet light which probably works under some conditions and not under others. Any microorganism which it is hoped will be killed by this form of energy must be directly exposed and not imbedded under the surface. Ultraviolet light has low penetrating power.

Mold inhibitors in the form of chemical salts are also used in some foods. Chief among these are the calcium and sodium salts of propionic acid which have shown considerable effect in bread and cheese. They are also incorporated in paper in which butter is wrapped.

Preservation of Molds. Microbiologists are always searching for improved methods of preserving cultures. Stock cultures must be maintained in vigorous condition from which cultures may be made when needed. The usual procedure is to use ordinary culture media, such as plain or carbohydrate agar. Other methods have been proposed. One such by Greene and Fred¹³⁰ for molds is an adaptation of one by Barthel¹³¹ for yeasts and bacteria. It involves use of sterilized soil in which the molds can grow and survive. Greene and Fred used air-dried orchard loam soil with sufficient added water to bring it to a moisture content of about 20 per cent. The soil is then added to half-inch culture tubes in five-gram quantities. These tubes are plugged and given four three-hour sterilizations at 15 pounds per square inch pressure on alternate days. A few may be tested by addition of yeast-water-glucose-broth. The tubes may be inoculated

with one ml. of a heavy spore or mycelium suspension and held at room temperature. Greene and Fred were able to maintain three species of molds for over two years, without loss of characteristics.

YEAST AND YEAST-LIKE FUNGI

Yeasts are microorganisms which are able to decompose carbohydrates into alcohol and carbon dioxide; they are unicellular and reproduce in two different ways. They are of special interest to food microbiologists. Certain species are used as leavening agents in bread; others are used in the vinegar fermentation and the manufacture of beverages. They are also of interest in the spoilage of certain foods, such as honey, tomato products, etc.

The methods used for cultivating the yeasts in the laboratory differ but slightly from those used for the bacteria. The fact that the yeasts desire acid in their metabolism is made use of in many media for favoring their growth and repressing the development of bacteria. Much difficulty is encountered by those who try to identify pure cultures of the budding fungi. They soon find that many of the descriptions in the literature are only approximately correct. Such work is also made confusing by the fact that more refined methods of working are available today. This is especially true for the determination of reactions of media.

Ascospore Formation by Yeasts. Ascospores are formed in some yeast cells. They are formed in a case or sac called an ascus. The presence or absence of asci and ascospores are used as differential characteristics of classification. Ascospores are formed in yeast cells probably for the same reason that spores are formed in bacterial cells. They may function to carry the cell over unfavorable periods or as reproductive units. It is quite well established, however, that ascospores are not as resistant as spores of bacteria. By means of ascospores fermenting species of yeasts are believed to survive the winter in the soil of vineyards and orchards. That ascospores are resistant stages in the life-cycle of the yeast is evidenced by the fact that the laboratory methods for demonstrating them are, in general, unfavorable to rapid development. They are cultured on media which are not entirely adequate.

While the knowledge that the composition of the medium may greatly influence the appearance of ascospores in yeasts has been known for a long time, much may still be learned from investigations. Kufferath¹³² studied the subject with many varieties of yeasts. In most cases a slightly alkaline medium was more favorable to sporulation than was a slightly acid one. The difference was less marked as the concentration of the medium rose. An increase in sporulation with alkaline media was reported for the following species: *Saccharomyces cerevisiae*, *Saccharomyces logos*, *Saccharomyces occidentalis*, *Willia anomala*, *Pichia farinosa* and *Pichia vini*. *Endomyces capsularis* was not affected by the reaction. *Schizosaccharomyces pombe* and *Pseudosaccharomyces apiculatus* sporulated as well on acid media. Kufferath also stated that temperature was very important.

132. Kufferath. 1930. Ann. Soc. Zymol., Pure and Appliquee 2, 33.

He believed that sporulation was a sexual phenomenon, and, consequently, any factor that affected chromosomal formation, would influence it.

The presence or absence of asci and ascospores and the method of formation when they are present are used by the taxonomist as characteristics for classification. In the Hansen-Guilliermond classification, it will be seen that ascospore formation is the important characteristic for making two large families *Saccharomycetes*, or true yeasts, and non-*Saccharomycetes*, or false yeasts. The former form asci and ascospores while the latter do not. *Saccharomycetes* are then subdivided according to the method of spore formation. Marchand¹³³ reported that in the majority of yeasts all traces of sexuality have been lost, but three cases were known (the yeast *Johannisberg* II, *Saccharomycodes ludwigi*, and *Willia saturus*) in which, although the formation of the ascus takes place parthenogenetically, the germination of the spores was preceded by conjugation. Marchand found that *Saccharomyces intermedius* (*Pastorianus* II), *Saccharomyces turbidans* (*Pastorianus* III), *Saccharomyces ellipsoideus*, and *Saccharomyces validus* behaved similarly. Conjugation occurred within the ascus, but only with about 50 per cent of the spores. In many cases the membrane of the ascus broke before this stage was reached, and then the spores developed without conjugation. These results show that, with yeasts, conjugation of spores is not exceptional, and it may possibly serve as a means of distinguishing certain yeasts; for example, *Saccharomyces pastorianus* from *Saccharomyces intermedius* and *Saccharomyces turbidans*, for the first-mentioned one forms parthenogenetic spores only.

Sexual union of the cells in certain species is now known to precede the formation of the ascus. This was seen probably for the first time by Schiönning who reported that asci in *Schizosaccharomyces octosporus* resulted from the fusion of two cells. Guilliermond¹³⁴ stated that this fusion was a true copulation. By using cells in hanging drops in moist chambers, he was able, after a few days, to observe the union of cells by a copulation canal formed by the union and fusion of two little projections from the cells. There is an intermingling of cell contents which results in the formation of a zygospor by isogamic copulation. These cells eventually germinate and grow in size. The nucleus divides into four or eight nuclei which surround themselves with protoplasm to form ascospores.

Guilliermond also reported heterogamic copulation in *Zygosaccharomyces chavalieri*. The asci resulted from copulation between cells of different size. A very small one functions as the male gamete while a larger one as the female. This latter is much older and has approached maturity. The two cells unite by a copulation canal and the contents of the male gamete is poured into the female gamete. Nuclear fusion takes place, resulting in the formation of one to four nuclei from which the ascospores are formed.

Hybridization of Yeasts. Fertilization and sexual processes were demonstrated in yeasts many years ago by Hansen and confirmed by Guilliermond and others. The full significance of these observations to industries

133. Marchand. 1912. Compt. Rend. Soc. Biol. 72, 410-412.

134. Guilliermond. 1901. Compt. Rend. Acad. Sci. 133, 242-244.

involving yeasts was not appreciated because modern genetics had not been developed at that time and there was no technic with which single cells of microorganisms could be isolated under the microscope. The latter was made possible by Barber¹³⁵ and others since, who developed apparatus for single-cell isolation under the microscope. This technic has more recently been used for breeding new yeast types through hybridization by Winge and Lausten.¹³⁶ They showed that sporulation of a yeast is associated with a genetic segregation which makes the spores in any ascus differ genetically. Sporulation in yeasts is considered to be quite comparable to formation of gametes in higher plants and when two ascospores fuse during germination, as has been known for some 50 years, this is a regular process of fertilization. On account of this, Winge pointed out the uncertainty that a pure culture of yeast, even if it originates from a single yeast cell, will keep uniform. If the yeast forms spores, entirely new types may segregate when the spore germinates. Winge proved this in the case of many species of *Saccharomyces* by isolating all four ascospores in one ascus, under the microscope, and making them germinate. Pure cultures developed from these ascospores differ distinctly. While segregation in sporulation involves morphological characters, physiological characters may also be involved. It is this possibility that gives Winge's work such import in the industries. It may be possible by segregation to breed a yeast with properties of special importance to a single industry. Winge made this significant statement:

"When we keep in mind that all high-breeding in higher plants and domestic animals has taken place through crossing and subsequent selection of the more superior individuals, it seems obvious that from now on there may be a chance also for a rational high-breeding of yeasts. Previously one had to be content to select the superior types among the ones that Nature has produced herself, but now it seems possible by crossing rationally to try to combine the desirable characteristics of several yeast types into a single new type."

Copulation of ascospores in yeasts has been observed for many years. Marchand¹³⁷ discussed it for various common species.

Demonstration of Ascospores in Yeasts. This is more difficult than the detection of endospores in bacteria. Several different methods have been proposed. Some of them are given below.

Hansen's Gypsum Block Method. This is the method usually advised for demonstrating ascospores in yeast cells. However, it leaves much to be desired since there are probably methods which yield more certain results. The plaster of Paris block may be made by pouring wet plaster of Paris into a cone of paper. After it has begun to set, the paper may be removed and the top of the cone cut off to give a flat surface on which to place the yeast cells. After the cone has been cut off, the block should be placed in a Petri dish or Esmarch dish, a little water added, and the dish sterilized in the autoclave. The yeast cells should be placed on the block with a loop and allowed to remain there for 30 to 48 hours, when ascospores are supposed to appear in the cells if the species forms them.

Gorodkova's¹³⁸ Method. This method consists essentially in growing the yeasts on a special agar. The formula for preparation of this agar is given in Chapter 26. It is a medium somewhat deficient in nutrients. Cultures of ascospore-forming yeasts on this medium were rich in ascospores while the same organisms on five per cent dextrose media were devoid of spores.

Maneval's¹³⁹ Method. Maneval noticed that cakes of compressed yeast that were kept in the ice box for six or eight days showed abundant spore formation in cells from the outer layers of the cake. The spores were easily demonstrable by mounting them in a drop of Gram's iodine solution and examining under a microscope with a magnification of 600 diameters.

Stained preparations were made as follows:

1. Spread a film in a small drop of water on a slide and dry in the air.
2. Fix by passing through the flame 12 to 15 times.
3. Stain with hot carbol fuchsin one to three minutes.
4. Wash with water.
5. Decolorize with five per cent sulfuric acid for two to three seconds.
6. Wash with water.
7. Stain with methylene blue about three seconds.
8. Wash and examine.

The spores should be stained a bright red, and the vegetative protoplasm blue. Much greater abundance of spores followed the propagation of pure cultures of yeasts on Maneval's modification of Gorodkova's agar. Very good spore formation took place in four to five days; in eight to 12 days 50 per cent of all cells developed spores.

Carrot slants have also been found to stimulate ascospore formation in yeast cells. The slants should be prepared in the same manner as potato slants. The slant should be inoculated with the yeast and kept at room temperature.

McKelvey's¹⁴⁰ Medium for Demonstrating Ascospores in Yeasts. Details for the preparation of this medium were not given. It was stated, however, that carrot agar, saturated with calcium sulfate, was suitable for the development of ascospores.

Lindegren's Method¹⁴¹ for Producing and Demonstrating Ascospores in Yeasts. This is one of the most successful methods for the purpose which the author has seen. The medium on which the yeast is grown consists of equal portions of bottled grape-juice and canned apricot juice (nectar) to which 3 per cent agar is added along with an excess of calcium carbonate. This medium is tubed, sterilized and slanted. A slant is inoculated with the yeast and allowed to grow for 48 hours or more. Full growth on this medium, according to Lindegren, occurs within 24 hours but he advises leaving the culture for another 24 hours or longer since some of the by-products of fermentation accumulate and are removed with the yeast cells to the gypsum slant. An increased number of spores are obtained. Lindegren believes that in addition to proper nutrition, it is necessary that certain by-products be present in the water saturating the gypsum blocks. Then 1 ml. of sterile water is added to the slant and the growth washed from the slant to the bottom of the tube. This suspension is then transferred to the top of a plaster of Paris (gypsum) slant in a test tube and the yeasts allowed to develop for about 24 hours.

The gypsum slants are prepared by mixing 100 gms. of plaster of Paris with 110 ml. of water. About 10 ml. of this mixture are placed in a large culture tube about 8 x 1 inch and slanted. These slants should then be dried at about 60°C. (140°F.) for 24 hours, plugged and sterilized. After inoculation with yeast suspension about 5 ml. of sterile water are placed at the bottom of the slant to moisten the gypsum slant.

Ascospores were stained by Lindegren by preparing a film on a glass slide with some of the growth on the gypsum slant. The film is fixed with heat and then placed in carbol-fuchsin in a Coplin jar for 30 minutes or longer. Destaining is accomplished

by holding the slide with forceps in 30 per cent acetic acid. One or two quick swishes are sufficient. The slide should not be rinsed before destaining. This prevents formation of a precipitate on the slide if it is put into water from the staining fluid. If the slide is left too long in the acetic acid solution or not rinsed quickly enough in water, it will be completely destained. Success of this method depends largely on careful control of destaining. After the rinse in water, methylene blue staining fluid may be used as a counter stain. Ascospores will then appear as deep red bodies among cells which are stained blue.

Resistance of Yeasts to Unfavorable Agents. Yeasts, like other organisms, are endowed with characteristics which make them capable of resisting unfavorable conditions. To temperature, however, they do not seem to be so resistant, although those species which possess spores are able to withstand boiling for a few minutes. They are able to survive much cold since they live through the winter in the soil, even in fairly cold climates. The spores of yeasts are responsible for their resistance, although the spores are probably not so resistant as the spores of the bacteria and molds.

Resistance of Yeasts to Freezing. The effect of freezing on yeasts has not received much study, at least under conditions which give information concerning their longevity, rate of death, etc. Doemens¹⁴² exposed beer yeast to a temperature of about $-190^{\circ}\text{C}.$ ($-310^{\circ}\text{F}.$) for six minutes. It still retained its vitality. When he suspended the yeast in water and exposed it to liquid air for five minutes and 20 minutes, and then thawed in cold water, its power of development was totally destroyed. Macfadyen and Rowland¹⁴³ subjected microorganisms, among which were yeasts, to a temperature of $-252^{\circ}\text{C}.$ ($-421.6^{\circ}\text{F}.$) for six months, after which the yeasts were reported to have suffered no reduction in vitality. They gave good growth and possessed unaltered powers of fermentation. One would infer from this report that yeasts are resistant to freezing and that there was no reduction in numbers. Bokorny¹⁴⁴ kept a sample of brewers' pressed yeast at a temperature of $-15^{\circ}\text{C}.$ ($5^{\circ}\text{F}.$) for 24 hours, and then allowed it to warm up slowly to a temperature of $7^{\circ}\text{C}.$ ($44.6^{\circ}\text{F}.$); fermentation and reproduction went on for a short time but soon stopped. In another experiment the yeast was very quickly warmed to $10^{\circ}\text{C}.$ ($50^{\circ}\text{F}.$); after four weeks in a suitable medium it exhibited slight fermentation. Microscope examination at this stage showed that most of the cells were dead and only a few were budding. Bokorny thus showed that beer yeast was resistant to cold, but not as resistant as other microorganisms.

Tanner and Williamson,¹⁴⁵ working with eight species of yeasts, found that there was a rather rapid death rate during the early periods of freezing. In 160 weeks, at from -13 to $-15^{\circ}\text{C}.$ (8.6 to $5^{\circ}\text{F}.$), there was a rapid decrease in number of viable cells. Some of the suspensions had been entirely sterilized during that time. Irish and Joslyn¹⁴⁶ reported that yeasts survived freezing in grape juice for 18 weeks and that their vitality was not lowered. Lange-Pozdeeva¹⁴⁷ reported that a temperature of -1 to

—170°C.(30.2 to 1.4°F.) killed most of the cells of Race XII, distillers yeast and pressed yeast, during the first eight to 12 hours after which the decrease in viable cells was slow. Freezing in water had greater destructive effect than freezing in must. Intermittent freezing and thawing had a more marked effect than continuous freezing. The method of storage at low temperatures influenced the vitality of the yeast.

Resistance of Yeasts to Ultraviolet Light. Yeasts are not very resistant to ultraviolet light, although there is some variation in response to it by various strains. Buchta,¹⁴⁸ Feuer and Tanner,¹⁴⁹ Nadson and Phillipov,¹⁵⁰ Tanner and Ryder,¹⁵¹ and Lindner¹⁵² published results of investigations which confirm this statement. The rapidity of destruction was found to vary with conditions under which the experiments were carried out. Feuer and Tanner noticed that pigmented yeasts were more resistant than unpigmented species. Lindner and others reported that in order to secure rapid destruction of yeasts, they must be exposed in thin layers. Substrates containing colloidal substances are not as easily penetrated as are clear substrates. This fact has been overlooked in some investigations.

Resistance of Yeasts to Heat. The budding fungi are not as resistant to heat as are some of the bacteria, especially those which form spores. However, yeasts are occasionally found in food products which have been heated, and it becomes important to know how the species involved react to high temperatures. Kayser¹⁵³ found that yeasts are more resistant in the dry state than in the moist state. Cochran and Perkins¹⁵⁴ tested the resistance of yeasts in sugar solutions of varying densities reporting that the cells were killed more quickly in the more dense solutions. This has not been the observation of Dougherty¹⁵⁵ and Rahn¹⁵⁶ whose reports are discussed below. Wells¹⁵⁷ investigated bread for living yeasts and was able to demonstrate viable cells in three of 20 specimens. Living cells were found in bread baked at 66°C.(150.8°F.), but not in bread baked at 68°C.(154.4°F.). It has been generally assumed that yeasts could not survive heating for more than 10 minutes at temperatures between 50 and 60°C.(122 and 140°F.). Hansen reported that strong young cells of *Saccharomyces ellipsoideus* II were killed by heating for five minutes between 54 and 56°C.; old cells under the same conditions were said to survive for longer times. Matured spores of the same species, partially dried on gypsum blocks, withstood 62°C., but not 68°C. Similar experiments with *Saccharomyces cerevisiae* I showed that strong young cells resisted 52° but not 54°C. Each species has its own temperature relations, as would be expected. Kayser¹⁵⁸ found that *Saccharomyces mali* Duclaux was

killed at 55°C.; Johnson¹⁵⁹ found *Saccharomyces thermantitonus* to be especially resistant to heat. Other data may be found in the publications of Will, Owen,¹⁶⁰ and Bay (1893). The data are frequently a little unsatisfactory because the time is frequently omitted. Dougherty¹⁵⁵ carried out a number of experiments in the author's laboratory. Twenty-four species of budding fungi were heated in various menstrua such as varying concentrations of salt and sugar, plain broth, distilled water, vinegar, etc. None of the species were destroyed at 40, 43, or 46°C. (104, 109.4, or 114.8°F.). Heating at 58°C. (136.4°F.) for 10 minutes caused the death of most of the species. *Willia belgica*, *Torula monosa*, and *Parasaccharomyces thomasi* were especially resistant to heat when heated in broth and milk. *Torula monosa* was killed only by heating the milk suspension at 98°C. (208.4°F.) for 10 minutes. Five species (*Mycoderma vini*, *Parasaccharomyces thomasi*, brewers' yeast, *Saccharomyces anomalous*, and *Cryptococcus ludwigi*) were heated in vinegar. Only *Parasaccharomyces thomasi* survived and then for only 10 minutes. The five species just mentioned were heated also in 5, 10, 15, 20, 30, 40, 50, and 60 per cent solutions of cane sugar and in 5, 10, 15, 20, 30, and saturated solutions of sodium chloride. The data secured with these solutions were quite similar. In no case was death of the cells more easily accomplished in the solutions with more sugar and salt. If anything, there was a tendency for the yeasts to possess greater longevity when heated in the more concentrated solutions. Rahn¹⁵⁶ published a note showing the sparing effect of concentrated solutions of sugar on yeasts when they are subjected to heat. He stated that it would take more heat to kill a yeast cell in a sweetened fruit juice than in an unsweetened juice. In this respect, he confirmed more definitely the observation that yeasts did not die as quickly when heated in concentrated sugar solutions as when heated in unsweetened solutions. Another bit of information on the subject was published by Ayers, Barnby and Voight¹⁶¹ for *Mycoderma* causing clouding of the brine in which olives are packed. This species was destroyed in five minutes at 54.4°C. (130°F.). Townsend and Powers¹⁶² found a yeast in spoiled canned orange juice which resisted 76.7°C. (170°F.) for one minute. More information on this subject will be found in Chapter 19.

Longevity of Yeasts. This is a subject of much practical importance. Information on it appeared in the early days of microbiology. Kayser¹⁶³ called attention to the fact that longevity of microorganisms depends on many factors, such as supply of oxygen, presence of moisture, hydrogen-ion concentration, exposure to light, and temperature. The necessity of pure cultures in fermentology caused Pasteur to report that brewery yeast, when dried and mixed with plaster of Paris, retained its vitality for 10 months. Duclaux, however, reported that such yeast remained viable for 15 years

when kept in beer, in which it had been cultivated. The same investigator showed that yeast in the dry state, kept in the dark, was not alive after 23 years; spores of *Aspergillus niger* lost their vitality even in three years.

In November, 1889, Kayser placed yeasts and mixtures of spores and yeasts upon bands of sterilized paper in test tubes. The yeasts were top fermentation brewery yeasts, a wine yeast, and *Saccharomyces pastorianus*. One-half of the tubes were placed in the laboratory exposed to diffused light, and the other half in an incubator at 28°C. (82.4°F.). Every three months a suitable medium was added to a certain number of tubes and the development of yeasts noted. *Saccharomyces pastorianus* was not alive three years later, but its spores were capable of germinating up to four years; the other three yeasts continued to germinate for four years. Their spores were killed in five years. Kayser also found the fermenting ability to be unimpaired by such treatment. Will¹⁶⁴ reported that yeasts remained viable many years in 1 per cent sucrose solutions in Freudenreich flasks. Meissner¹⁶⁵ suspended 25 species in 10 per cent sucrose solutions, and seven years later found that nine had died. Other cultures were quite devitalized, for they showed signs of growth only after a long time. Results of an investigation by Tanner and Burrows¹⁶⁶ were in accord with those of Meissner. Klöcker¹⁶⁷ found that most cultures were capable of remaining viable for at least 30 years, but that some died in much shorter time. Klöcker stated that sucrose solution was not a suitable medium for preservation of some yeasts.

Another method, the utility of which is not fully appreciated by microbiologists, was suggested by Barthel.¹⁶⁸ It has been shown by many that yeasts are able to survive for long periods in soil in nature. Without reviewing the results which Barthel presented, it may be stated that microorganisms so preserved seemed to remain as active as those preserved by other methods.

The most recent method to be used is lyophilization—freezing in a vacuum. Various types of apparatus have been devised for applying this method to yeasts and bacteria.

Distribution of Yeasts in Nature. That yeasts are quite widely distributed in nature seems to be borne out by the fact that fermentable materials usually contain many different species without inoculation with pure cultures. Pasteur¹⁶⁹ was one of the first to show this. Hansen¹⁷⁰ subjected this statement to critical investigation and reported yeasts in soil throughout the year. Furthermore, inoculation of soils with yeasts indicated that they could endure low temperatures. Hansen's results were nicely confirmed by Müller-Thurgau,¹⁷¹ Berlese,¹⁷² and Ludwig.¹⁷³ The

last-mentioned investigator reported yeasts to be commonly present in vineyards, as did Hansen. They were believed to be carried to the fruit by dust, insects, rain, etc.

Budding fungi have also been found in the air by Biacosa (1883), Nakazawa,¹⁷⁴ and others. Nakazawa stated that a strong wind seemed to increase the number in the air.

This subject has also been of significance in spoilage of honey by yeasts. Many of the investigators who have studied this question have tried to determine whether the flowers visited by bees during the honey season harbor osmophilic yeasts. Reukauf,¹⁷⁵ Stoltz,¹⁷⁶ Schuster and Ulehla,¹⁷⁷ and Jimbo,¹⁷⁸ among others, have been able to show the presence of yeasts in flowers. Lochhead and Heron¹⁷⁹ reported yeasts in practically all of 34 different kinds of flowers. The above data show the wide distribution of yeasts in flowers, and the probability that they are disseminated by insects. Budding fungi are just as widely distributed as are other fungi.

CLASSIFICATION OF YEASTS AND RELATED ORGANISMS

Two general methods have been used for classifying yeasts. One is used by industrial fermentologists who are not especially interested in taxonomic problems. According to this method, pseudoscientific names are used, such as beer yeast, yeast XII, etc. The other method is used by botanists who try to give every organism a name which connects it with a larger group and also serves to identify it. It is unfortunate that so little attention is given to taxonomy by fermentologists.

Grouping of Yeasts in the Industries. The yeasts are grouped according to some salient characteristics, such as pigment-formation, or according to the special use to which they are put. Below are given a few of these names.

Distillers' Yeast. Distillers' yeasts usually differ from types used in other industries. These yeasts form greater amounts of alcohol and are grown in different kinds of substrates. Distillers' yeasts are not grown in hopped wort like the brewery yeasts. On the other hand, the distillers' yeast shows greater activity in flour and water than brewers' yeast. This has been explained by some fermentologists as due to the toxic action of flour, or some of its constituents, on brewers' yeast.

Top Yeasts. These are species which ferment at the top of the substrate. Such yeasts are distillers' yeasts, and those usually used in breadmaking. The separation of yeasts into the two varieties, top and bottom yeasts, is not a sharp one, and consequently confusion exists on this subject.

Top yeasts have been said to contain less trypsin than bottom yeasts and consequently do not reduce the carbon dioxide retaining ability of the dough. They also contain more amylase. Many experiments have been carried out on the change of top yeasts into bottom yeasts. Changes in the opposite direction are more rare. Rathke and Windisch¹⁸⁰ stated that even in a pure culture of one or the other kind, cells of the opposite kind may be produced, and the two types may continue to develop side by

side in the same nutrient liquid. The cause of the change and the conditions which bring it about are not understood.

Bottom Yeasts. These types ferment at the bottom of the culture tubes. This type is often called sedimentary yeast, on account of its accumulation at the bottom of the culture tubes. When these yeasts are used in brewing, a lower temperature is also used. Consequently, fermentation proceeds more rapidly while growth and reproduction proceed more slowly. Bottom yeasts are poor in amylase and excrete more trypsin than do top yeasts.

Distinction of top from bottom yeasts is not clear-cut. Rommel¹⁸¹ was unable to detect any distinctive features between top and bottom fermentation yeasts. Top yeasts were found to possess somewhat higher ash content than bottom yeasts; they also possessed higher specific gravity than bottom yeasts. The differences, however, were not sharp. Hansen at an earlier date, showed that under some conditions some bottom yeasts could be converted into top yeasts. Changes in the other direction were said to be more rare. The evidence on which the latter change was based consisted only in the non-formation of head by supposedly bottom yeasts. Schönfeld and Rossman¹⁸² reported that permanence of this property may be questioned. The rate of respiration was reported by Trautwein and Wassermann¹⁸³ to distinguish top and bottom yeasts. The rate for top yeasts was on the average 77 per cent higher than bottom yeasts. Top yeasts were said to rise to the surface during fermentation, where they can find oxygen and thus become acclimated to an aerobic existence. These authors stated that 40 per cent of the total metabolism of top yeasts was respiratory and 60 per cent fermentative, while with the bottom yeasts the ratio was 32 and 68 per cent respectively. Hansen was able to develop top yeasts from bottom yeasts by growth at low temperatures. Winge and Lausten's¹⁸⁶ spore-segregation method discussed above has made it possible to produce the reverse change.

Brewers' Yeast. Brewers' yeast, since it is used for a different purpose, has special properties. It is used for leavening bread to some extent, but imparts certain undesirable characteristics to the bread. It is darkened considerably. Brewers' yeast is also less active than the bakers' yeast, and if used for leavening must be used in larger amounts.

Classification of Yeasts. Yeasts are Ascomycetes which have many affinities in other groups of fungi. This has made classification quite difficult. Hensen¹⁸⁴ suggested a classification which has been used by many workers since then; it was later modified by Guilliermond.¹⁸⁵ Another modification was made later by Zender¹⁸⁶ because of the discovery of a new species of *Endomyces*. The latest contribution to classification of yeasts is by Stelling-Dekker¹⁸⁷ and Lodder,¹⁸⁸ the former dealing with sporeformers, and the latter with nonsporeformers. These last-mentioned classifications present entirely new arrangements with new family, genera, and species names, as does one by Langeron and Talice.¹⁸⁹ Asporogenous yeasts have been classified by Lodder.¹⁸⁸ Some of her suggestions are given later in this chapter under *Torulopsis*.

Identification of Yeasts. This is a very unsatisfactory if not difficult procedure. For some of the characters which must be determined, there

is no satisfactory technic. Furthermore, the student may have to make many observations before satisfactory convincing evidence is available. Negative results are always unsatisfactory. If one desires to identify the strain under study, it is best to study the characteristics of similar yeasts which have been reported in the literature or to secure a transplant from the type culture. The latter is always preferable if its authenticity can be established. In many cases, the original strain has been lost and only the description in the literature is available. This is frequently of little value on account of ambiguous, indefinite statements. Reactions of media may be given without stating the indicator; resistance to heat may bear only the temperature without any statement of time, etc. In order to facilitate the study of yeasts, Guilliermond ¹⁸⁵ prepared an outline of technic which may be used.

METHODS FOR STUDYING YEASTS

Yeasts are microorganisms which are grown much as the bacteria are grown. They differ by the fact that they are able to tolerate acid; consequently, if a little organic acid is added to the medium, the yeasts will grow while the bacteria will not. In Chapter 26 are given numerous formulas of media and solutions for cultivating yeasts.

Microscope Study of Yeast. Such examinations are constantly made by fermentologists to control the activity, purity, etc., of their yeast. The cells should be single or in pairs and not in large masses. If this condition exists, it indicates an immature yeast since the cells have not grown large enough to break away from the mother cell. The cells should be of about the same size and not vary from giant cells to small ones. Very young yeast is also evidenced by very thin cell walls and old yeast by very thick walls. The cells should also be intact and not show signs of breaking up. Such a yeast will, of course, be weakened in bread making. Young yeast cells should show one or two vacuoles when placed on a slide in wort. Poorly nourished yeast cells, also, have very thin walls and thin watery fluid contents instead of the thick walls and a gelatinous granulated protoplasm (Jago).

The microscope study of yeast cells may be made by mounting a little of the yeast in a warm chamber in a little wort. They should be watched over a period of time to ascertain the changes which take place in the cell as fermentation begins. For this purpose, the microscope should be kept in a warm place. The same observations should be made over a period of a week with some of the yeast in a culture flask. The constitution of the new cells should be compared with that of the cells which were first used.

Hansen's Single-Cell Method for Cultivating Yeasts. Hansen devised a method for securing single cells of yeasts. It was based on the method used by Lister for counting bacteria in milk. A special cover glass ruled in squares was used. One drop of the liquid dilution of the yeast cells was placed on the cover glass within the limits of the large square. The small squares only assisted in counting. This cover glass with the hanging drop was then fixed to a glass ring on a slide and the number of cells counted. If the drop was found to contain 20 cells it was then introduced into 40 ml. of sterile water. This would give approximately one cell in each two ml. of the water. The diluted

yeast could then be introduced into flasks and each flask would probably contain a single cell although this was not always attained.

Lindner's Drop Culture for Testing Yeast. This method when applied to compressed yeasts, will give information on purity in a short time. The yeast is diluted with sterile wort until each drop contains one cell. Then a number of these droplets are placed on a sterile cover glass and inverted over a ring to make a Böttcher moist chamber. Development may be followed and inoculations made into other suitable media. Vuckovic¹⁹⁰ modified this procedure as follows: The original culture is suspended in either water or physiological sodium chloride solution. One small drop of this suspension is then transferred to a microscope slide and examined with the microscope. If the drop is found to contain only a few cells, about three, it may be transferred with a sterile loop to the surface of one or more agar slants. If the number of colonies which subsequently develop corresponds to the number of cells previously seen in the droplet, each can safely be considered as a single-cell colony.

Lindner's Adhesion Culture. According to this method, which was first stated by Lindner,¹⁹¹ a thin layer of the yeast culture adhering to a cover glass is placed in a moist chamber. The yeast cells thus develop in their natural medium. It has various possibilities. It may be employed to determine the types of microorganisms on the outside of a piece of fruit. A little water would be put on the cover glass and the fruit pressed into it.

Microscope Examination of Pressed Yeasts. Prepare a thin mixture of the yeast in distilled water. To this mixture or a small portion of it, add a little of a .1-per cent solution of methylene blue. Mount a drop of this under a cover glass on a slide and enumerate the dead and living bacteria. The dead cells will stain but the living cells will not. Henrici¹⁹² found that yeast cells retained Gram's stain more firmly than the common Gram-positive bacteria. It has been further shown that, unlike the bacteria, the cytoplasm of the yeast cell is not homogenous with regard to its ability to retain the stain, certain granules appearing in the decolorizing cell which hold the dye longer than others. It is suggested that the ability of these granules to resist decolorization is in direct proportion to their ability to resist autolysis.

Boas¹⁹³ believed that bakers' and brewers' yeast differed sufficiently to make it possible to tell whether bakers' yeast has been falsified with brewers' yeast. Colingsworth and Baldwin¹⁹⁴ observed numerous small areas of discoloration owing to growth of various yeasts, molds, bacteria, and actinomycetes when various brands of pressed yeast were held at room temperature for four to six days. Frequently, numerous black areas of about one millimeter in diameter appeared. The organism associated with the black areas was found to resemble the organisms which are commonly referred to as "black-yeasts." On culture media, yeast-like cells of the organism contain a black pigment in the cell wall. A white mycelium is formed under certain conditions. Destruction of sugar does not result in formation of appreciable amounts of acid or gas. On most media the organism grows very slowly. A medium was developed for the detection of small numbers of this organism in the presence of numerous cells of *Sac-*

Saccharomyces cerevisiae. A mannitol yeast-infusion agar, to which copper sulfate was added to give a two-per cent concentration, permitted good growth of the "black yeast" but inhibited the growth of various other organisms, especially *Saccharomyces cerevisiae*. With this medium, three of four "black yeast" organisms per milliliter could be detected, although millions of other organisms were present in the sample. Commercial yeast cakes were found to contain from four to 100 "black yeast" cells per gram.

Strength of Physiological State of Yeast. In the fermentation industries it is necessary to have active, healthy yeast. This is especially desirable if pure-culture inoculation is used for introducing the yeast. Henneberg¹⁹⁵ stated that physiological state of yeast is chiefly characterized by its enzyme content, its enzyme-forming ability, and its chemical composition. He proposed a method for determining the "growing power" of individual cells. The yeast was treated with a solution of sucrose in distilled water. A droplet of the yeast suspension was examined after a lapse of 24 hours, under the microscope, in order to determine how often the individual cells have budded, numerous countings being made in order to obtain average values. The yeast is stimulated in this method to activity by the sugar; since there is no material for the formation of new protein, the yeast must employ its reserve protein. In this manner, its activity measured by its growing power is an indication of its physiological state. With the yeasts studied, Henneberg found that the growing power was dependent on the degree to which the yeast was washed. Higher "growth numbers" (i.e., ratios of numbers of cells observed after 24 hours to the numbers initially present) were obtained with a large inoculum since (1) foreign matter adheres to the cells despite washing and (2) extractives from dead cells can probably be used. With a still larger inoculum growing power showed a great decrease or disappeared altogether on account of too-rapid fermentation of sugar. The alcohol formed exerts a toxic action. Henneberg reported "growth numbers" from 1.16 for a top "Weissbier" brewery yeast, to 4.57 for nonaerated, Race XII species. The highest number produced from one cell was 11, while the average of the maximum numbers in different experiments was 5.1. It is very interesting from a biological aspect, that one cell can store so much reserve material that it is sometimes able to bud from five to 11 times. Well-nourished, ordinary yeast, as well as well-nourished aeration yeasts, present growing numbers of 3 to 4.5. Insufficiently nourished, pressed yeast, prepared by the aeration process, and also old yeasts present low growing numbers. Further investigations will show what are the conditions that influence budding. For practical purposes, and especially in the manufacture of yeast, the growing test appears to be of considerable value. The more a yeast cell can grow without addition of nitrogenous matter, the better is its quality; and the greater the proportion of vigorous cells in the yeast mass, the greater must be the value of the latter. A yeast containing a large proportion of immature, badly-nourished, or old, half-starved cells

is unsuitable for practical purposes. Such cells, when introduced into worts or mashes, must first assimilate much nutriment before they can bud, and the result is that both the quantity and the quality of the yeast crop suffer. The enzyme content and the enzyme forming power of such yeasts is small, so that these yeasts are useless for baking purposes. An active yeast is one which contains a good energy reserve (reserve protein) and can, therefore, begin budding or fermenting at once. Dietrich¹⁹⁶ placed some of the burden on the medium. Sugars, proteins, and mineral substances, should be present in the wort in the right amounts. Oxygen absorption and the right temperature were other factors of vital importance. If these factors are not right, the yeast will be poorly nourished and will degenerate. The microscopic appearance of such yeast is characterized by alteration in shape with a tendency for the cells to elongate. The protoplasm is more or less granular and contains droplets of oil.

Characteristics of Good Compressed Yeast. 1. It should be moist, but not too much so.

2. Should not be too dry—so much so that it is powdery.
3. Should be well mixed and not show striated areas of different colors.
4. Should dissolve readily in the mouth and not remain as a lump.
5. Should have a pleasant, aromatic odor and pleasant taste.

The compressed yeast cake contains, besides the yeast cells, numerous bacteria. Since the yeast cells are present in such large numbers they overgrow the bacteria. However, if the yeast is kept at a warm temperature, the bacteria may spoil the yeast. Henneberg¹⁹⁷ found lactic acid and acetic acid bacteria. Russell¹⁹⁸ also found that the bacteria which cause ropy bread may also be present.

Conditions under which pressed yeast is stored seem to influence its fermenting ability. Storage at low temperatures preserves its activity to a marked extent as shown by results of experiments by Larmour and Brookington¹⁹⁹ and Bailey, Bartram, and Rowe.²⁰⁰ The former found that storage of pressed yeast on ice resulted in improvement of its activities. Bailey, Bartram, and Rowe (1932) in quite extensive experiments concluded the pressed yeast should be stored around $-1.1^{\circ}\text{C}.$ ($30^{\circ}\text{F}.$). Frozen yeast made good bread at first but deteriorated rapidly and yielded progressively poorer bread as it was stored.

Detection of Yeasts in Foods. In some foods yeasts are known to be present and special effort must be made to repress the growth of other microorganisms and favor their development. This may usually be done by using a medium made acid with such acids as acetic, lactic, and tartaric. In the chapter on "Media" are given some formulas for media made acid with lactic acid. In the case of agar media, the lactic acid solution must be added after sterilization, else the solidifying properties of the agar will be destroyed. The acid solutions should be sterilized

separately and added to the melted agar aseptically. The acid in the media will favor growth of yeasts but repress growth of bacteria.

Examination of Yeast. It is often necessary in the fermentation industries to examine yeast in order to determine its fermenting ability, purity, contamination, etc. Two general types of yeast are recognized—cultivated yeast and wild yeast. Cultivated yeasts are those which have been propagated under controlled conditions and the characteristics of which are well known. They usually have a beneficial effect on the fermentation. Wild yeasts are made up of contaminating varieties and they usually cause the many undesirable fermentations (diseases) often encountered.

Pressed yeast is often made from top fermentation species; the water is removed and the cells mixed with some inert substance, such as starch and lactose. Effort is made not to use yeast of the bottom fermentation type on account of the absence of amylase and the presence of active trypsin. When trypsin-forming yeasts are used, the proteins are attacked, which interferes with retention of carbon dioxide. The use of a species which does not produce trypsin causes a tough glutenin which easily retains the carbon dioxide. Schweizer stated that pressed brewery yeast (bottom fermentation yeast?) was more active in dough in the early stages but the fermentation stops when bakers' yeast is still active. Pressed brewery yeast was said to be more sensitive to salt than is bakers' yeast, the fermentation of the two kinds being arrested by 2.8 and 4.0 parts of salt per 100 parts of flour respectively. Schweizer suggested that 2.8 per cent of salt be used for testing the value of the yeast in breadmaking. Harrison²⁰¹ made an investigation of yeast, finding that distillery yeast was superior for breadmaking to some of the so-called bread yeasts. Lindet²⁰² reported that one gram of bakers' yeast contained between five and six million cells. Such data are influenced, of course, by many factors. He also found that one gram of dough from the same bakery contained about the same number of cells.

Differential Staining of Living and Dead Yeast Cells. When the microscope was used for counting microorganisms, results secured with it were criticized because living and dead cells could not be differentiated. Investigations were soon started to discover a method by which living and dead cells could be differentiated. These, in general, have been staining methods.

Some investigators use a .1-per cent aqueous solution of methylene blue for this purpose. Schlichting and Winther²⁰³ studied the common methods used for this purpose and reported that they were not accurate enough. They found that different concentrations of stain gave different results. They preferred a solution of sulfo-indigotate in a dilution of 1-30. The most appropriate dilution of yeast was one with about 40,000 cells per ml. Haehn and Glaubnitz²⁰⁴ pointed out the difficulties of interpreting the results of staining suspensions of yeast with methylene blue. If all of the cells are absolutely dead or absolutely sound, staining will indicate it, but if cells are present which are neither completely dead or sound, but merely weakened, the difficulties are apparent. Some of the cells which stain blue are able to ferment and even regenerate themselves. These facts were demonstrated with a healthy yeast which had been weakened with acid. Even though the cells stained blue, they were not dead, but fermented as

201. Harrison. 1902-03. Ontario Agr. Coll. and Expt. Sta. Bul. 118.

202. Lindet. 1910. Ann. Brass. et Dist. 13, 155-164.

203. Schlichting and Winther. 1910. Seventh Internatl. Cong. Appl. Chem. 6B.

soon as they were put into wort. Haehn and Glaubnitz²⁰⁴ stated that the concentration of the stain influenced the number of cells stained. The greater the concentration of dye, the greater was the number of stained cells. These investigators reported that the best concentration of dye was 1 to 10,000. Counting was advised immediately after addition of the staining solution to the yeasts. If the counts were delayed for 15 minutes after the dye was added, the number of stained cells was three times as great. Furthermore, Haehn and Glaubnitz recommended thorough mixing, because the condition of yeast varies with its position in the cake. Fuchs²⁰⁵ recommended that the concentration of methylene blue should not exceed one part in 10,000 when testing yeast for dead cells. He also stated that the test was best carried out on washed yeast, after the wort or culture fluid had been removed. If the yeast is suspended in wort a larger amount of staining solution has to be added to produce a distinct blue color, e.g., three volumes of staining solution to one volume of suspension, because the colloids of the wort take up part of the dyestuff. As a rule, while some of the cells take a deep stain, others are only faintly colored. Fuchs' experiments indicated that the former are really dead, but the latter may still be capable of reproduction, and it is probable that the faint staining is due to a layer of mucilaginous matter on the cell walls. If a yeast suspension remains a long time in contact with an excess of the staining solution a number of cells which are at first uncolored become stained in the course of hours or days. In some cases the staining is gradual and in others very sudden, as if a rent had formed in the cell wall. The number of cells which thus die in the course of one or two days depends naturally on the age of the original culture. Dead cells stained with methylene blue may, if suspended in water, become bleached again after a time. This is due to the action of the reductases which may remain active after the cells are dead. The bleaching is much more rapid in wort, owing, doubtless, to the acidity of the wort; for equally rapid decoloration is produced by a .2-per cent solution of lactic acid or a 2-per cent solution of monopotassium phosphate.

Studies on the Bios question, in which it was very desirable to know whether cells were dead or alive, stimulated considerable study of the effect of various stains on yeasts. Fraser²⁰⁶ employed a large group of stains, including many which are commonly used in the bacteriology laboratory. The action of these stains was determined on "boiled" and "live" bakers' yeast, and on yeast mixed with .25 per cent of phenol. Erythrosin gave a sharp separation between living (stained red) and dead (colorless) cells in three minutes, and methylene blue in one minute, after the addition of the dye. Devereux and Tanner²⁰⁷ also reported erythrosin in .25 per cent aqueous solution when mixed with a yeast suspension to be the most efficient and desirable of 10 stains examined. It has been recently stated²⁰⁸ that results obtained with the use of stains for differentiating living and dead cells are greatly influenced by the conditions which obtain during the experiment. The pH value of the liquid in which the yeast cells are suspended was said to influence their staining properties. The fact was mentioned that methylene blue was a base, the hydrochloride of which is soluble in neutral or acid solution, while in alkaline solution the less soluble free base is set free and is available for adsorption. The electrolytic content of the liquid was also mentioned as an influencing factor. It is not clear to what extent this is due to a corresponding change in pH value, since the presence of certain substances, such as dextrose and

levulose, predispose the yeast to staining. A number of electrolytes inhibit staining in various degrees, and it may be that their absence renders the yeast cell walls more permeable to the stain. Standard conditions of staining cannot therefore be formulated for all strains of yeast, and it seems desirable to study further possible substitutes for methylene blue. Erythrosin, methyl green, and methylene blue sharply differentiated living and dead yeast cells in Mill's²⁰⁹ experiments. A solution containing 1 to 10,000 methylene blue is best for differential staining.

Nadson and Burgwitz's²¹⁰ Method for Determining Fermenting Power of Yeasts. The complicated and expensive apparatus required for the determination of fermentative power, according to the methods of Hayduck, Meissl, or Kleinschmidt, induced Nadson and Burgwitz to put forward a cheap and simple contrivance, the construction of which was described in detail.

An Erlenmeyer flask with cork stopper is closed by a head-piece consisting of a U-formed bent glass tube of 3.4 to 4 mm. internal diameter, the limbs being of different length. The longer juts into the flask and the shorter is led into a small glass cylinder through a cork stopper, and so placed that the shorter limb reaches to within a millimeter of the bottom of the cylinder, which is from one-quarter to one-third full of dilute sulphuric acid ($5 \text{ H}_2\text{SO}_4 \cdot 7.5 \text{ H}_2\text{O}$). In making the estimation, the apparatus is first sterilized, liquid and yeast then introduced, corks vaselined, sulphuric acid poured into the small cylinder, and the complete apparatus weighed. The carbon dioxide passes out through the sulphuric acid, leaving behind the alcohol and water, and escapes by the slit in the side of the cork cylinder. Before weighing,²¹¹ on conclusion of the fermentation period, the carbon dioxide must be removed by careful shaking. The loss of weight of the apparatus is taken as equal to the carbon dioxide evolved, and this is adopted as a measure of the fermentative power of the yeast. The apparatus is unsuitable for work of great accuracy or for experiments of long duration, and it should not be used where widely-changing temperatures or humidities occur. Nevertheless, it is easy to handle and for ordinary technical purposes does not yield to more complicated and more expensive apparatus such as that of Meissl.

Efficiency of Bread Yeasts. This may be determined in different ways. A representative sample of the yeast should be obtained and divided into three parts. Store separately at 20, 30, and 40°C. (68, 86, and 104°F.). At regular intervals test each part for dead cells, gas formation, and dough-rising power. Test once or twice for adulteration with beer yeast and with mycoderma.

Dough-Rising Power of Bread Yeast. Mix 100 grams of flour, two grams of yeast and 60 ml. of distilled water by first making a thin batter of the yeast, water, and a little of the flour. Then add the rest of the flour and knead for five minutes. About three grams of flour should be kept with which to clean the glass rod. The dough should be molded into a cylinder and dropped into a warmed graduate cylinder which has been greased or powdered with flour. Press the dough down into the cylinder and place at 30°C. The volume is read every 30 minutes until the maximum is reached. Compute the maximum volume in terms of the original. Plot a curve which will show the activity of the yeast.

Determination of Fermenting Power of Yeasts, Meissl²¹² Method. A saccharose phosphate mixture is prepared as follows: 400 grams of saccharose, 25 grams ammonium phosphate, and 50 grams of calcium sulfate. To 4.5 grams in 50 ml. of tap water of this substrate in an Erlenmeyer flask, fitted with a Meissl ventilation valve, add one gram of the yeast. Concentrated sulfuric acid may be used to absorb the H_2O , thus

allowing the CO_2 to escape. The flask with inoculated contents should be kept at 30°C . for six hours. Meissl reported that a normal yeast would form 1.75 grams of carbon dioxide. The fermenting ability of such a yeast would be taken as 100 and the activity of the yeast under investigation as a percentage of this. The fermenting ability of an average bread yeast is about 80 per cent. Different types of valves are available. Alwood²¹³ used a convenient type for studying the fermenting capacity of pure strains of yeasts. The valves are so constructed that the activities of the yeast may be observed and the gases from the fermentation may escape. The moisture is retained by some absorbent such as calcium chloride or sulphuric acid. The apparatus should be weighed before and after the test.

Holm's²¹⁴ Method for Detecting Mycoderma and Mycoderma-Like Organisms in Yeast. Most of the Mycodermae and film-forming budding fungi which occur in distilleries and yeast factories are not alcohol-producing organisms, but generally decompose the alcohol formed by the yeast. Their presence in the pressed yeast weakens the latter and diminishes its commercial value. Yeast that has been prepared by the aeration process is especially liable to be infected with such Mycodermae. Holm described a simple and rapid method for the detection of Mycodermae in yeast, the essential feature of which consists in making a surface culture in which all the colonies will at once manifest their peculiarities. Ten or 20 small portions of yeast are taken, some from the surface and some from the interior of the yeast sample, with a sterilized needle or glass spatula, and transferred to a Freudenreich flask containing 10 ml. of sterile water. The liquid is shaken, and one or a few drops are transferred to a second flask also containing 10 ml. of sterile water so that the latter becomes very slightly but distinctly turbid. A second and a third dilution are made in the same way, the third being used for seeding. The most suitable medium consists of unhopped wort to which has been added five per cent of gelatin and $1\frac{1}{2}$ per cent of agar. The medium is liquefied, poured into a Petri dish (15 cm. diameter), and allowed to solidify. The contents of the flask containing the third dilution are then poured so as to cover the surface of the medium; to prevent aerial contamination, Hansen's infection box may be used. The water is left to stand for a moment on the medium and then poured off quickly, the dish is covered and placed horizontally (with the cover turned upwards) in a thermostat at 25 to 27°C . (77 to 80.6°F .). After one or two days the culture is examined, and it may be easily seen with the naked eye which colonies are formed by the yeast and which by Mycodermae; the latter are large and flat, and also differ from the yeast colonies in color. The percentage of each kind of organisms may be easily found by counting.

Hayduck's²¹⁵ Method for Testing Fermenting Activities of Yeasts. Hayduck measured the amount of carbon dioxide liberated by yeasts, volumetrically. To a mixture of 40 grams of sucrose in 400 ml. of water in a flask are added 10 grams of the yeast to be studied. This flask is connected to a gas burette; the culture flask is maintained at 30°C . for one hour. By the usual technic the number of ml. of carbon dioxide formed may be read off. The weight of sugar decomposed by 100 grams of yeast may be determined by multiplying the number of ml. of CO_2 formed by the factor .03841. According to Nägeli,²¹⁶ comparison of Hayduck's method for determining the fermenting power of pressed yeast with baking tests, showed that while on the whole the former method distinguishes correctly between good and bad yeasts, it often gives untrustworthy results respecting samples intermediate in quality. Better results are obtained if the following salts are dissolved in the 400 ml. of 10-per cent sucrose solution employed: two grams of acid potassium phosphate, one gram of acid ammonium phosphate, .25 gram of magnesium sulfate, and .20 gram of calcium sulfate. By means of the modified method, pressed yeasts may be divided into good baking yeasts, producing more than 1,000 ml. of carbon dioxide in two hours; medium yeast, producing 800-1,000 ml.; and

216. Nägeli. 1911. *Rev. in J. Inst. Brewing* 18, 132.

bad yeasts, producing less than 800 ml. Cook and Malloch²¹⁷ pointed out some of the conditions which must be maintained if accurate results were to be obtained.

Determination of Fermenting Power of Yeasts (Kusserow's Method²¹⁸). Put 400 ml. of 10-per cent saccharose solution and 10 grams of the yeast under examination into the fermentation flask of the Kusserow apparatus. Warm the flask and solution to 30°C. before starting. After the apparatus has stood for an hour at 30°C., it is connected and the amount of gas formed in the next half hour is measured; it should be 250 ml. The amount of gas for the first and second half hours is usually about 50 and 150 ml., respectively. Five grams of yeast in 400 ml. of 10 per cent saccharose solution in a flask fitted with a fermentation valve will cause a loss of about 6.5 grams of carbon dioxide in 24 hours if distilled water is used; with tap water the loss should approximate eight to 12 grams.

Another method for testing the fermentation ability of yeast involves the collection of the CO₂ evolved in a graduated container. The use of such a method is probably more accurate than the methods described above but has the disadvantage of requiring the maintenance of a constant temperature. Some liquid having a low absorption power for CO₂ should also be used. For this purpose a solution of calcium chloride of a specific gravity 1.4 may be used.

Determination of Mycoderma in Bread Yeast. Press the yeast with a sterile spatula into the bottom of a small Petri dish and incubate at 37°C. (98.6°F.) for two days. If the yeast contains a Mycoderma, pure white, characteristic colonies will appear on the yellowish background of the bread yeast. Numerous biological analyses of press yeast by Henneberg and Neumann²¹⁹ showed that 50 to 80 per cent of the yeast consisted of *Mycoderma cerevisiae* species. From the experiments made it was concluded that such a mixture of wild and cultivated species cannot be employed for making bread.

Test for Adulteration With Beer Yeast. Practically all of the beer yeasts ferment raffinose while the bread yeasts generally do not. One gram of the yeast is mixed with about 10 ml. of a one-per cent solution of raffinose broth and placed into a fermentation tube. Incubate this tube for about 24 hours at 30°C. A blank tube without raffinose should be prepared in order to test for gas produced from stored glycogen. If the difference between the two tubes is decided (about 50 per cent) adulteration with beer yeast is probable. A greater difference renders the test more conclusive.

Bau's Method for Testing the Purity of Yeasts. This determination depends on the fact that most bottom yeasts ferment raffinose while the top yeasts (compressed bread yeasts) do not. According to Bau²²⁰ the following technic is followed: Test tubes are filled with 10 ml. of a one-per cent solution of raffinose in plain broth, plugged, and sterilized. Then .4 gram of the yeast under study is inoculated into the tube, which is then incubated at 30°C. for 24 hours. At the end of this time the substrate in the tube should be filtered and three ml. of the filtrate tested with Fehling's solution. If the solution is not reduced and remains blue it is fair evidence of not more than 10 per cent of bottom yeast in the compressed yeast. This same test should be made after 48 and 72 hours with tubes which have been held for that purpose. If, however, Fehling's solution is reduced and a yellow or yellow-brown color appears, it indicates that the bread yeast (top yeast) is free from bottom yeasts. Keuttner and Ulrich²²¹ reported results which confirmed the reliability of Bau's method. On the other hand, Langfurth²²² stated that contrary to the observations of Keuttner and Ulrich, Bau's raffinose method only gives perfectly reliable results when a really pure culture, top-fermentation yeast is being dealt with; but, on the other hand, it gives erroneous indications with commercial

yeasts. Consequently, the method is incapable of determining whether beer yeast is present in pressed yeast. Saare and Bode²²³ reported Bau's method to be reliable.

Lindner's²²⁴ Method for Detection of Bottom Fermentation Beer Yeast in Pressed Yeast. The failure of Bau's method to satisfactorily separate top from bottom yeasts by melibiose fermentation caused Lindner to propose another method. According to Lindner, the most characteristic difference between top and bottom fermentation yeasts lies in the structure of the branches of their budding chains. To examine this, the yeast must be allowed to bud freely and unconfined. The yeast should be suspended in wort at such a dilution that, when droplets are prepared on a cover glass with a pen, each hemispherical pearl-shaped droplet contains not more than two or three cells. About 30 droplets containing about 100 cells are allowed to hang freely and are examined under the microscope after a period of not more than 24 hours. At that period the plant produced by the budding of each cell can be detected with ease and its characteristic form can be traced. The branches of the top-fermentation yeasts, so far as Lindner's experience goes, always grow in a sparlike formation. The top-fermentation yeasts bud with a monopodial ramification in which the original axis is continued as such. The bottom fermentation yeasts, on the other hand, bud with a sympodial ramification, in which the original axis suddenly disappears, while a side axis assumes the function of the main axis. If the yeast plants could grow upwards perfectly freely, the top-fermentation yeasts might be likened to fir trees and the bottom yeasts to birch trees. This method of diagnosis is the most reliable and occupies less time than other biological tests, the same series of observations can also be made to serve for the determination of the purity of yeast. In doubtful cases, where a confirmation is required, recourse may be had to the slower and less definite method of making a dilute streak culture of the sample of yeast with a point brush on a gelatin plate.

After the colonies have developed they should be picked off with a needle and stirred in a drop of water. As a general rule the colonies of top yeast will form a homogeneous turbid suspension in water, while those of bottom yeast tend to form a flocculent, clotted suspension in water.

Detection of Wild Yeasts in Pressed Yeast. This is not so necessary with the compressed yeast of the present day. It probably contains few bacteria and other objectionable fungi and a sufficient number of healthy cells. Hansen (1904), however, used a method for accomplishing this. A little of the yeast under investigation was inoculated into a tube of sterile wort and shaken in order to break up the cells. This culture tube was then incubated at 25°C. (77°F.) for 24 hours or for 48 hours at room temperature. After this time a growth appears at the bottom of the tube. This may be transferred several times to fresh tubes. Finally, some of this deposit is transferred to a sterile gypsum block contained in a Hansen flask or dish with a liberal supply of water. After from 40 to 72 hours an attempt should be made to determine the presence of spore formation. The presence of wild yeast is indicated by the presence of spores within this time.

Lindner's²²⁵ Method for Testing Homogeneity of Pressed Yeast. A sample of yeast may be said to be homogeneous when all the cells in the sample are approximately of the same size and appearance, belong to the same species, and are in the same physiological condition. When a growth of pure yeast is first started in the propagating apparatus, it is very rarely homogeneous, although it consists of a single species; it is therefore readily understood that such a yeast will give very different results in the fermentation tuns, as compared with a stock yeast which has been in use for a considerable time, and which is generally homogeneous. The process of washing the pitching yeast with water, as practiced in Germany, tends to eliminate the young budding cells of low specific gravity, leaving the heavy, agglomerated, and mature cells behind, thus favoring the homogeneity, which suffers if the washing be not properly performed.

223. Saare and Bode. 1903. *Wehnschr. Brau.* 20, 101-105.

224. Lindner. 1904. *Ztschr. Spiritusindus.*, 26, 229; Through *J. Fed. Inst. Brew.*

225. Lindner. 1904. *Wehnschr. Brau.* 21, 621-622; Through *J. Fed. Inst. Brew.*

In order to test whether yeast is homogeneous or not, a small quantity of the sample should be suspended in fresh wort and examined in droplet cultures ("Federstrich" cultures), note being taken of the form and tendency to budding, how many of the cells are still capable of budding, how many descendants are produced from each cell in a given time, and whether the descendants are alike or different. In some cases, the cultivation of the yeast in a thin layer of beer gelatin (Will's test) will afford valuable information, and it may thus be concluded, according to whether the colonies are mulberry-shaped or extend in streamers, whether the mother cells belong to the fermentative form or are film cells of the first or second generation; a preponderance of the latter forms indicates that the yeast has been exposed to the air to an excessive extent during its growth. The droplet test, if a standard number of cells be taken in each droplet, also gives a quantitative expression for the degree of infection with wild yeasts, and, according to the form of the budding chains, the presence of bottom-fermentation yeast in a sample of top-fermentation yeast can also be detected and estimated. When a sporulating yeast is examined in droplets, some cells may contain spores, while others in the same droplet may be devoid of spores, showing a lack of homogeneity in the condition of the yeast.

Detection of Starch in Pressed Yeast. Starch in pressed yeast may be detected with the microscope. The type of starch may be determined from the characteristics of the granules.

Many of the various species of yeasts are found in food and beverage products. In some cases, they are responsible for costly spoilage.

Schizosaccharomyces. The species in this group divide by transverse division. The first species to be reported was isolated from fruits by Beijerinck²²⁶ and described under the name *Schizosaccharomyces octosporus*. *Schizosaccharomyces mellacei* was discovered in molasses by Greg. The species in this group have in general been isolated from products from the warmer climates.

Zygosaccharomyces. Ascospores in the species of this group result from conjugations. While the species which have been described come from different sources, only those which are related to food products will be mentioned here. The more recently described species have been reported by Fabian and Quinet²²⁷ and Lochhead and Heron²²⁸ from honey. Richter²²⁹ described *Zygosaccharomyces mellis acidii* from fermenting honey. It was believed that the organism was contributed to the honey by the bees—a reasonable assumption. Fabian and Quinet described *Zygosaccharomyces mellis* and Lochhead and Heron *Zygosaccharomyces richteri* and *Zygosaccharomyces nussbaumeri* from the same source. Many of the species in this genus are able to live in concentrated sugar solutions.

Zygosaccharomycodes. This genus is of recent origin, having been made by Nishiwaki²³⁰ for a species (*Zygosaccharomycodes japonicus*) isolated from saké. As the generic name indicates, it combines characteristics found in the older genera *Saccharomycodes* and *Zygosaccharomyces*. Nishiwaki believed that the species studied copulated as do the *Zygosaccharomyces* and multiplied by a process intermediate between budding and partition. The genus is still too young for general acceptance.

Debaromyces. Members of this genus have been isolated from cheese, sausage, and soil. Some pathogenic species have also been described.

Nadsonia. This genus was made to take care of an unusual method of conjugation which takes place between a mother cell and a bud from it. It includes one species, *Nadsonia fulvescens*. All of the contents of one gamete, the male, are poured into the other, the female; later on the ascus is formed. Nadson and Konokotin (1912) proposed the generic name *Guilliermondia*, for these species.

229. Richter. Mycol. Centbl. 1, 67-76.

230. Nishiwaki. 1929. Centbl. Bakt., Pt. 2, 79, 194-204.

Schwanniomyces. Each cell possesses a single spore about which is a projecting collar. Many of the cells in a suspension of this species show the presence of a short tube or beak, giving the cell the appearance of a retort.

Torulaspora. This genus is not sharply distinguishable from *Schwanniomyces*.

Saccharomycodes. This genus was made for a very few species which divide by a process which is intermediate between budding and partition. Only a very few species are known. It is interesting to note that Nishiwaki²³⁰ found a species, *Zygosaccharomycodes japonicus*, which he thought sufficiently different to justify the new genus just mentioned.

Saccharomycopsis. Only one species has been described. Ascospores are formed. The cells are large. It has not been found in food products.

Saccharomyces. The members of this genus are important in the industries and are usually active fermenters. *Saccharomyces cerevisiae* is the best-known species and was studied at great length by Hansen. *Saccharomyces pastorianus* and *Saccharomyces ellipsoideus* are other species from fermented products.

These species are generally considered to be the best representatives of so-called "industrial yeasts." *Saccharomyces cerevisiae* is generally considered to be a round or oval-celled species with little ability to form alcohol, while *Saccharomyces ellipsoideus* possesses long cells and forms much alcohol. The latter has generally been known as the wine yeast. This distinction, based on work of Hansen, has been losing its significance as recently pointed out by Henrici.²³¹ Stelling-Dekker even went so far as to reduce *Saccharomyces ellipsoideus* to *Saccharomyces cerevisiae* var. *ellipsoideus*. Henrici was of the opinion that this idea might be applied to other industrial yeasts, although difficulties are encountered because industrial yeasts are often known for some special property, little attention being paid to species relationships.

Pichia. The members of this genus form mycelia and grow well on the surface of liquid culture media. Ascospores are formed. The genus is characterized by absence of fermentative activity. The shape of the cells of *Pichia* species is sausage-like.

Hansenula (Willia). The derby hat shape of the ascospores is the most characteristic thing about this genus. A thick film is formed on liquid culture media.

Monospora. Not much is known about this genus, but one species having been described. The ascospores are characteristic in that they are long and slender with sharp ends.

Nematospora. The ascospores of this genus are long and slender with a long polar flagellum at the end. Those species which have been described have come from food products. Those species which are known have come from hazelnuts, tomatoes, and string beans.

Torulopsis (Torula). Members of the genus *Torula* do not form ascospores and are, consequently, not considered to be true yeasts. Interest in the species of this genus started with the investigations of Hansen and several other early fermentologists. Like *Mycodermae*, *Torulae* are found widely distributed in saccharine material, even though they are generally nonfermenters. The group consists of two sections; one, the members of which are pathogenic and the other, the members of which are non-pathogenic.

Classification of *Torula* is in an unsatisfactory state. The term *Torula* was used by Turpin in 1838 for fungi which are now considered as *Sac-*

231. Henrici. 1942. *Brewers' Digest* 17, 34-36.

charomycetes. He called beer yeasts *Torula cerevisiae*. Hansen, however, with whose investigations started real progress on systematization of yeasts, included among the Torulaceae only those budding fungi which produced neither endospores nor typical mycelial vegetation. According to Hansen, only globular forms are found with perhaps occasionally elongated cells in films. He also stated that some Torulae can cause alcoholic fermentation. More recently, the Torulae have been studied by Ciferri and Redaelli²³² and Harrison.²³³

Ciferri and Redaelli's²³² Classification of Torulae. Budding fungi which do not form ascospores have been studied at some length by these investigators. They stated that they based their system on earlier ones, especially that of Will which has not been generally accepted by microbiologists. Only that part of Ciferri and Redaelli's classification which deals with Torulae will be reproduced here.

SUBFAMILY A.—TORULOPSIDAE

- | | |
|---|--|
| 1. Cells showing a vestige of copulation of the
germinative tubules | Genus 3. <i>Asporomyces</i> Chaborski. |
| Cells without traces of sexuality | 2 |
| 2. Apiculate cells (lemon shaped) | Genus 4. <i>Kloeckeria</i> Janke |
| Rounded, oval, elliptical cells, rarely apiculate
and then mixed with the foregoing | 3 |
| 3. Cells normally very small and without a clearly visible
double contour | Genus <i>Pityrosporum</i> Sabouraud |
| Young cells with one or more oleose corpuscles, grow-
ing according to Will's fundamental form I | Genus 6. <i>Eutorulopsis</i> Ciferri |
| Young cells without oleose corpuscles and growing
according to Will's form III | Genus 7. <i>Torulopsis</i> Berlese |

Harrison's²³³ Classification of Torulae. A great many species of budding fungi which did not form ascospores were studied by Harrison. He paid most attention to functional characteristics, especially fermentation reactions. Harrison could not accept Ciferri and Redaelli's classification because they paid no attention to priority in the use of names. Harrison preferred to follow Will's suggestion, which may be tabulated as follows:

- Mycotorula* = forming rudimentary mycelium.
Rhodotorula = red pigment.
Chromotorula = Yellow, brown, or black pigment.
Torula = no pigment formed.

Torulae have been reported from a number of foods. Browne²³⁴ isolated *Torula communis* from raw Cuban sugar. Wehmer²³⁵ described several from sauerkraut. *Torula mellis* was described by Fabian and Quinet²²⁷ from honey. Two interesting lactose-fermenting Torulae were isolated from "yeasty" cream by Hammer and Cordes.²³⁶ They were named *Torula cremoris* and *Torula sphaerica*. Hammer²³⁷ also described *Torula lactis-condensi* from swelled cans of condensed milk.

A more recent attempt to classify the asporogenous yeasts was by Lodder¹⁸⁸ who arranged them into the following groups:

232. Ciferri and Redaelli. 1929. Ann. Mycol. 27, 243-295.
 233. Harrison. 1928. Trans. Roy. Soc. Canada, Sect. V, 22, 187-225.
 234. Browne. 1918. J. Ind. Eng. Chem. 10, 178.
 235. Wehmer. 1905. Centbl. Bakt., Pt. 2, 14, 682-713.
 236. Hammer and Cordes. 1920. Iowa Agr. Expt. Sta. Res. Bul. 61.
 237. Hammer. 1919. Iowa Agr. Expt. Sta. Res. Bul. 52.

ASPOROGENOUS YEASTS

Family 1 (?) Nectaromycetaceae	Family 2 Torulopsidaceae	Family 3 Rhodotorulaceae
Producing conidia	No conidia produced. Carotinoid pigments not produced.	No conidia produced. Cells contain carotinoid pigments. Genus: Rhodotorula.
<hr/>		
	Subfamily A Torulopsoideae	Subfamily B Mycotoruloideae
	With or without a primitive pseudomycelium. No sporeforming organs.	With pseudomycelium and possessing sporeforming organs.
	Genera: Torulopsis Pityrosporum Mycoderma Kloeckera Asporomyces Trigonopsis Schizoblastosporion	

This arrangement will probably be generally accepted by microbiologists.

Mycoderma. Into this genus are placed species in which ascospore formation has not been demonstrated. This does not always mean that they do not form them but that they have not been observed. It is quite probable that some non-ascospore-forming strains of other species have been placed here. Mycoderma species usually grow with a heavy film or pellicle on the surface of fluid media, such as beer wart, pickle brine, and fruit juices. They often cause trouble by using the acids formed by bacteria, which are necessary in food preservation.

Pseudosaccharomyces. The cells of the species in this genus are lemon-shaped.

Sporobolomyces. This is one of the more recent genera of yeasts made by Kluyver and van Niel²³⁸ for several species which, while growing like true yeasts, later show a tendency to put out organs much like sterigmata at the tip of which conidia are formed. While Kluyver and van Niel described three species, others are known to exist. Since sterigmata are formed it was proposed to consider these fungi as Basidiomycetes in which Lohwag²³⁹ and Guilliermond²⁴⁰ did not agree.

Anthomyces. This genus was made by Nadson and Krassilnikow²⁴¹ for a species, *Anthomyces Reukaufii*, isolated from the nectar of flowers. In nectar pairs of cells were first formed and later groups of four; since the cells are club-shaped with their narrow ends in contact the groups have been said to resemble airplanes or crosses. When the cells separate they assume oval or round shapes, becoming filled with fat to form resting cells (Dauernzellen). Under some conditions of culture a mycelium is formed with conidia.

CHAPTER 4

BACTERIOLOGY OF WATER AND SEWAGE

By collecting data from the large registration cities of the United States Johnson¹ in 1916 gave ample proof that polluted water caused illness. During recent years, however, relation of water to disease dissemination has been diminishing progressively. Milk probably causes more epidemics now than water. Bacteria in water may also be significant in industry. They cause undesirable deterioration in certain foods. Harrison and Sadler,² for example, stated that *Pseudomonas fluorescens* caused discoloration of halibut. Shutt³ found the same organism the cause of flavor deterioration in pasteurized creamery butter. Shutt³ stated that a water supply might be satisfactory for human consumption but be unsuitable for butter making. A serious defect caused by several types of bacteria, among which *Pseudomonas fluorescens* is most important, results in the development of disagreeable odors and flavors over the whole surface of butter. It gains access to water from surface drainage especially from swamp lands. The only permanent solution is to pasteurize or chlorinate the water or obtain it from a pure source. Shutt mentioned a creamery so affected where the water supply seeped through vegetation to collect in ditches filled with large stones. The surface flavor bacteria disappeared when the water was collected directly from springs. Surface taint of butter was traced by Linneboe⁴ to *Achromobacter putrescens* in water supplies of creameries. This has been confirmed also by Wolochow, Thornton, and Wood⁵ who found in creamery waters many bacteria which could grow at 10 to 15°C. (50 to 59°F.). Many were actively proteolytic. These investigators thought that waters used in creameries might have to be given bactericidal treatment. The same opinions were also expressed by Castell and Garrard.⁶ Salting butter to the extent of 2.5 per cent, did not prevent these waters organisms from growing (Turgason⁷). Heavy chlorination was required to destroy them.

Possible infection of food by contaminated water is indicated by Meyer, Phillips, Lind, and Board⁸ who traced a milk-borne outbreak of typhoid fever to this source. Water from a cistern used for washing utensils contained *Eberthella typhosa*. Many such instances might be mentioned. Even water from deep wells may be polluted.

Heater⁹ reported an interesting case where polluted water from a well 155 feet deep was responsible for typhoid fever. A small stream of water

was encountered during drilling, which was not cased off. Ten years afterward, owing to a typhoid outbreak, a connection between the well and an abandoned quarry was discovered. Lewis¹⁰ reported coliform bacteria in fissure springs of the Balcones fault zone in Texas. He ascribed this contamination to animals pastured on the plateau on which the water was collected. Other industries may also suffer from objectionable bacteria in their water supplies. According to Feys¹¹ various methods may be used for treating such water.

Besides the troubles just mentioned there are some of lesser importance; for instance, Green, Judd, and Marx¹² attributed "ropiness" in tea to a capsulated bacterium present in the water from which it was made.

Sanitary Inspection of Water Supplies. Sanitary inspection is an important part of water-supply investigation. Laboratory results alone are not sufficient to judge quality of a water supply. Sawyer¹³ quoted an instance of a water-borne epidemic which could have been prevented had a sanitary inspection been made. Indications of pollution appeared two months before the epidemic broke out. A sanitary inspection would probably have prevented seven deaths and many cases of typhoid fever. Laboratory examinations should be used to check the results of remedial measures, when such measures are adopted. Cobb¹⁴ suggested the use of the engineering point of view and more attention to sanitary inspection than to bacterial analysis. This might reveal sources of coliform bacteria not revealed in any other way. Water mains, for instance, if new or recently repaired, may be contaminated. Harris¹⁵ recommended chlorination of such mains before use. Contamination was said to be possible from fecal matter of careless workmen or from jute or hemp packing as well as from other sources.

Types of Water. Chemically speaking, water is hydrogen monoxide and regarded as a universal solvent. Only with the greatest difficulty and with the most carefully constructed apparatus can the chemist prepare water which approaches pure hydrogen monoxide and be free from all traces of metals, salts, gases, dust, or bacteria.

Different adjectives are used to indicate quality of potable water—pure, safe, polluted, infected, bad, etc. To the sanitarian, a pure water is one which is free from pathogenic bacteria and which has had a good clinical experience. It should also be free from chemical substances, such as lead and fluorine, which cause disturbances in the body. This subject is complicated somewhat by the fact that individuals vary in their response to different waters. A water which is wholesome to one person may cause severe disturbances in another. Rosenau, in his *Preventive Medicine and Hygiene*, classified waters as good, polluted, and infected. A *good* water was defined as above for pure water. A *polluted* water was one which had

received organic wastes of either man or animal. Such a water is not necessarily harmful. An *infected* water is one which contains disease-producing microorganisms.

Relation of Chemical to Bacterial Examination. In the past, discussion has centered about superiority of the chemical or bacterial analysis of water. Much of this has probably been quite useless since both are important and necessary for an accurate opinion on potability. The more information at hand, the more accurate will be the opinion. The chemical analysis may give information about the history and possibly the age of the water. It gives information about the content of organic matter and the stage of its decomposition, as indicated by the nitrogen compounds present. It enables the sanitary engineer, for instance, to maintain sufficient alkalinity in the water to prevent alum used in its purification from passing into the filtered water. Chemical analysis also detects objectionable trade wastes, the presence of heavy metals, and indicates to some extent how water may be expected to behave in the human body.

The bacteriological examination is made to determine the kind and number of microorganisms present. It is easy to conceive that a water of good quality by chemical analysis might contain pathogenic bacteria. While isolation of specific pathogenic bacteria from water is not attended with much success, the bacterial examination yields more definite knowledge of their possible presence than can be obtained by chemical means. Bacteriological examination is especially important also for determining the efficiency of filters and the value of other methods of treatment. Negative results in the bacteriological examination might have little significance.

For our purposes, sanitary water analysis may be regarded as made up as follows:

- I. Sanitary chemical examination
 - A. Physical (organoleptic) tests
 - a. Turbidity
 - b. Color
 - c. Odor
 - B. True chemical determinations
 - a. Residue
 - b. Chloride
 - c. Nitrogen as
 - 1. Nitrates
 - 2. Nitrites
 - 3. Free ammonia
 - 4. Albuminoid organic ammonia
 - d. Alkalinity
 - e. Oxygen consumed

Collection of Samples. Collection of the sample of water is an important part of the analysis. It must be done carefully. For chemical analysis, samples should be collected in glass-stoppered bottles which are scrupulously clean. The stoppers should fit tightly and be protected during transportation. For bacteriological analysis, four-, six-, or eight-ounce, glass-stoppered bottles, cleaned and sterilized, should be used. They should

have been rinsed in water and sterilized thoroughly either at 160°C. (320°F.) for one hour, or for 30 minutes at 15 pounds pressure. Before shipment, the top of each bottle should be protected by a piece of cloth or tin foil. Specimens for bacteriological analysis should probably be packed in ice during transportation (Hasseltine¹⁶). Instructions for sampling usually accompany the bottle. Schmidt¹⁷ also gave procedures for collecting water samples.

Interval Between Collection and Analysis. Analysis of samples of water should be started as soon as possible after collection. Since changes may occur in the sample, certain examinations may be made in the field. The committee which prepared the 1917 *Standard Methods for the Examination of Water and Sewage* suggested the following as being within reasonable limits.

Physical and Chemical Analysis

Ground waters.....	72 hours
Fairly pure surface waters.....	48 hours
Polluted surface water.....	12 hours
Sewage effluents.....	6 hours
Raw sewage.....	6 hours

Microscopical Examination

Ground waters.....	72 hours
Fairly pure surface waters.....	24 hours
Waters containing fragile organisms.....	Immediate examination

Bacteriological Examination

Samples kept at less than 10°C.	24 hours
--------------------------------------	----------

The committee which prepared the 1925 edition of *Standard Methods* placed a time limit, between collection and analysis, of six hours for impure waters and not more than 12 hours for relatively pure waters. During the storage period the temperature should be kept between 6 and 10°C. (42.8 and 50°F.). It is stipulated that any deviation from this shall be stated in the reports.

Identical recommendations appear in the eighth edition of *Standard Methods of Water Analysis*. Water bacteriologists have frequently stated that samples should not be held very long before analysis. Eijken¹⁸ reported that changes occurred even at 0°C. (32°F.). Despite this opinion most of the samples analyzed in large central laboratories are shipped, and some time interval exists between collection and analysis. It is probable that a general rule should not be applied to all samples for their bacterial flora differs. Berry¹⁹ found no change in the number of coliform bacteria in samples of ground water in the first 48 hours after collection regardless of whether the samples were iced or not. Uniced samples were said to yield dependable results. Ellison, Hackler, and Buice²⁰; McCrady²¹;

21. McCrady. 1920. Idem 7, 845-851.

Tanner and Schneider,²² and perhaps some of the results secured by Boruff and Buswell²³ confirmed this opinion. McCrady described a mailing case for sending water samples for analysis. Castell and McDermott²⁴ condemned this procedure. Their results with it were too erratic.

Other investigators have reached different conclusions. Kelso²⁵ exchanged a series of samples with three laboratories to determine the effect of mailing uniced samples. Plate counts increased materially after 24 hours; after 48 hours the counts were lower than after 24 hours. It was stated that examination of uniced samples gave results of doubtful value. Effect of shipping was not pronounced in the finished water but was noticeable in the raw water.

Keiper and Flinn²⁶ observed that higher counts and greater coliform-bacteria content were secured with samples sent through the mail. Such samples were not considered to be satisfactory.

Analysis by Caldwell and Parr²⁷ of 50 replies from state and insular laboratories indicated that in most cases the procedure prescribed in *Standard Methods of Water Analysis* for storage and time of examination of water samples is not observed; a large number of samples were examined after 24 hours and a considerable number after 48 hours. Comparison of recovery of coliform bacteria from iced and uniced samples examined at varying periods indicated a very rapid death rate of *Escherichia coli* in bottled samples of contaminated waters, which was progressively greater as the period of holding increased. Icing, though of secondary importance, was definitely advantageous.

Chemical constitution of the water apparently has much effect on results of storage of water samples. Few who have worked on the problem have considered this factor. Castell and McDermott²⁴ observed that growth in water of low organic content was restricted to certain groups of Gram-negative bacteria. They showed the danger of delaying analysis of samples too long, especially if results are to be considered in terms of food spoilage rather than potability.

Boruff and Buswell²³ were among the few to point out that the type of water and other factors may influence the results. They observed that icing of warm waters caused a marked decrease in the total count. On the other hand, warm waters with a low total count frequently were said to increase slightly in total count when iced for short periods. Boruff and Buswell found little change in total counts of cold water—1 to 4°C. (33.8 to 39.2°F.)—when such samples were collected from rivers and brought to the laboratory and incubated at 2°C. (35.6°F.) for one to five days. These data indicate that icing may have profound effect on the bacterial content of samples of water, depending on the source of the sample and the time of year when it is taken. Other factors also help to explain the

27. Caldwell and Parr. 1933. *Amer. J. Pub. Health* 23, 467-472.

discordant results which have been secured by so many different investigators. The best practice is probably to continue icing samples until more evidence is available that it is unnecessary.

Effect on Bacterial Count of Shaking the Sample. *Standard Methods for the Examination of Water and Sewage* have, for many years, prescribed shaking vigorously for 25 times. Green's²⁸ work would indicate that vibrating (frequency of 60 per second) instead of shaking is more desirable on account of higher counts secured. The increase in bacterial numbers was 67 per cent. It is questionable whether such matters really affect the plate count more than the inherent errors in the method itself.

Data Required With Specimens Submitted for Analysis. Laboratories engaged in water analysis require complete information about the source of the sample. This information is usually supplied on a certificate which accompanies the sample bottles and is necessary for accurate interpretation of results of examination. Failure to supply it usually means delay and in no manner increases the value of the opinions of the laboratory. Most laboratories will not report results and opinions without full information. This is a sound practice.

BACTERIOLOGICAL EXAMINATION OF WATER

The main purpose of bacteriological examination of water is to determine the presence of microorganisms which may cause deterioration in foods or which may produce diseases in man and animals. Owing to difficulties in isolation of pathogenic bacteria with certainty within a reasonable time to be of any value, bacteriologists have developed another procedure of testing for presence of bacteria which live in the human intestines along with pathogenic bacteria, should they be present. This is the test for coliform bacteria. It is not an ideal procedure but an expedient. Hoskins and Butterfield²⁹ have stated that a satisfactory procedure to determine promptly and satisfactorily when a water is free from pathogenic bacteria does not exist. In some cases too much emphasis may be given to bacteriological methods of analysis. Howard³⁰ pointed out, for instance, that a negative bacteriological result may not be a guarantee of safety. Further positive findings may not indicate human pollution because it is quite impossible to distinguish accurately between human and animal pollution. Despite these shortcomings, considerable progress has been made with bacteriological methods.

Bacteriological methods are, in general, used for determining quality of potable water. These do not involve attempts to isolate specific pathogenic bacteria but to demonstrate the presence of bacteria which originate in fecal matter, sewage, and other types of contamination. Methods for isolating pathogenic bacteria from water are not entirely satisfactory and pathogenic bacteria may not live as long in water as the indicators of pollution. Present practice seems to be more concerned with showing that

possibilities of pollution exist than in showing that disease-producing bacteria are present. In pages to follow various indicators of pollution and procedures for demonstrating their presence are discussed.

Significance of Bacterial Count of Water. In the early days of laboratory examination of water, the bacterial count was thought to be a reliable index of pollution. Many standards, based on counts, were formulated for determining quality. An elaborate but quite useless one was suggested by Miquel.³¹ Probably Koch's old standard of not over 100 bacteria per ml. on gelatin is as reliable as any. High counts in themselves are probably meaningless. However, water with a consistently high count stands a greater chance of containing objectionable forms. In natural waters, a high content of organic matter is usually accompanied by a higher number of bacteria.

Two methods were used in the past for enumerating water bacteria. A 37°C.(98.6°F.) colony count was secured with agar plates incubated for 48 hours and a 20°C.(68°F.) colony count on gelatin after 24 hours' incubation. It was believed that at 37°C. those forms which originated in the alimentary tract of man and animals would develop, while at 20°C. the soil forms would develop. Later, it was found that the colony counts secured at both temperatures overlapped greatly. The relative merits of the two procedures have been discussed by Whipple,³² Caird,³³ Baton,³⁴ Gaub,³⁵ Harrison,³⁶ Cumming,³⁷ Tanner,³⁸ and Race.³⁹ Most of these papers, published about the same time, were stimulated by suggested changes in "standard methods." Hoskins,⁴⁰ and Frost and Streeter⁴¹ observed season variations in counts as well as in the relation of the gelatin count to the *Escherichia coli* count.

Little agreement exists on the number of bacteria which may be allowed in a safe potable water. The bacteria themselves are not important but the conditions which they reflect are important. In the fourth edition of the *Swiss Alimentary Codex*⁴² for bacteriological and chemical analysis of water, the counts are below 100 bacteria per ml. for spring water and 10 per ml. for ground water. *Escherichia coli* must be absent in 20 ml. of spring water and in 100 ml. of ground water.

The plate counts secured in water analysis are markedly influenced by the media used. Not as much study has been given to media to be used in water analysis as in milk analysis. Gurfein,⁴³ after a comparative investigation of various proposed methods, concluded that not over 50 per

cent of the organisms developed into colonies in beef infusion-peptone agar media.

Introduction of a new plating medium for counting bacteria in milk, which gave more colonies than the old medium, prompted Mallmann and Breed⁴⁴ to study its use in water analysis. Counts with the new medium were relatively high when parallel old standard agar plates were sterile. The difference in counts was not considered to be sufficient to require changes in standards. Such a position would seem to indicate that the bacterial count has little significance if it can vary from zero to "relatively high." This is probably the case, for a few pathogenic bacteria would be absolutely significant when a great number of harmless saprophytes would not.

The intervals between analyses should be as short as possible for supplies serving many people. Results of a single analysis are of doubtful value whether they are satisfactory or not. Frequent and regular examination of large city water supplies, or supplies in important food-preservation industries, is the best practice. Results of any examination merely indicate the sanitary condition at the time when the sample is taken.

Dilution Water in Bacteriological Water Examination. Many samples of water must be diluted before plating. Usually distilled water or tap water is sterilized in known amounts for this purpose. Several publications have suggested that the type of dilution water used is important. Distilled water buffered with sodium and potassium phosphates at pH 7.2 was suggested by Butterfield⁴⁵ as a suitable and easily prepared synthetic dilution water. Distilled water and waters with a pH of 9 or over were found to be harmful to bacteria. Besides hydrogen-ion concentration, mineral salt content is important. Butterfield believed that such tests should be made only after sterilization because dilution waters are changed by heat. It is apparent from this work that more attention should be paid dilution waters, for bacteria may die rapidly in some.

American Public Health Association Procedure for Colony Count. These recommendations include details of careful bacteriological technic which have been found necessary for accurate results. All sample and dilution bottles shall be shaken 25 times before samples are removed for plating. Plating shall be done immediately after dilutions are made. One ml. of sample is placed in a sterile Petri dish and 10 ml. of standard nutrient agar are added. Incubation follows immediately after the medium has hardened at 20°C.(68°F.) for 48 hours or 37°C.(98.6°F.) for 24 hours. When nutrient gelatin is the plating medium, the plates are incubated at 20°C. for 48 hours. When results are reported the medium used shall be stated.

Irrespective of the procedures used to obtain the colony or cell count of water, as well as foods in general, the results are quite likely to vary widely. Good practice suggests that amounts of water be used which will give between 30 and 300 colonies on a plate. This cannot always be done and the analyst must then use his best judgment in securing the colony count. *Standard Methods of Water Analysis*, Eighth Edition, 1936, p. 209, suggested a method for reporting the number of colonies of bacteria per ml. of water to avoid fictitious accuracy and yet express the results with reasonable

45. Butterfield. 1933. Pub. Health Repts. 48, 681-691; J. Bact. 23, 355.

precision. This suggestion concerns only a method for reporting counts. They are probably of no more significance than if they were reported in a different manner.

Ministry of Health,^{45a} Great Britain, Procedures for Plate Count of Water. The following is an abstract of the official procedure:

Diluent. Tap water may be used provided it is free from any marked germicidal activity. Distilled water, prepared in glass (not metal) stills, is permissible. One-quarter strength Ringer's solution is preferred.

Preparation of Dilutions. Shake the bottle 25 times by a rapid rotatory movement of the wrist and, after flaming the mouth of the bottle, pour off one-quarter of its contents, reinsert the stopper, and shake 25 times with an up-and-down movement. One, two, or rarely three dilutions, according to the nature of the sample, each 10 times the previous one, should be made in dilution bottles or in test tubes by carrying over a suitable quantity of water to nine times its volume of diluent, mixing thoroughly, and repeating if necessary. Either bottles or test tubes may be used as diluent receptacles. Only nine ml. of diluent are used in the latter. Specific instructions are given for handling the pipettes and transferring portions.

Inoculation of Plates. Two Petri dishes are to be inoculated, each with one-ml. portions from the second dilution, if one has been made, and four plates from the original water. Again explicit instructions are given for handling the pipettes and making dilutions.

Each Petri dish then receives 10 ml. of melted, cooled nutrient agar. The plate is rotated five times and then given five to-and-fro movements. The plates are then cooled and placed in the incubator.

Incubation of Plates. Two of each set of four plates made with original water and with 1-10 dilution should be incubated at 37°C.(98.6°F.) for two days, and two at 20 to 22°C.(68 to 71.6°F.) for three days, in each case bottom upwards. The two plates made with the 1-100 dilution should be incubated at 20 to 22°C. for three days. Temperature should be checked in air incubators and the air should be kept moist. Care should be used to prevent plates near the source of heat from becoming too hot. If plates are stacked, they should be staggered to permit good air circulation.

Counting of Plates. Plates incubated at 42 to 48°C.(107.6 to 118.4°F.) should be counted in from 42 to 48 hours. Those with from 30 to 300 colonies should be selected for counting. They should be counted within four hours after removal from the incubator, or placed in a refrigerator. The plate should be examined with a magnifying glass of four inches focal length, giving a magnification of two and one-half diameters. A specially constructed box which allows examination by combined reflected and transmitted artificial light against a dark background is recommended.

The plates incubated at 20 to 22°C. are to be counted after 66 to 72 hours.

Reporting Results. Plate-count results are reported not as the number of organisms per ml. but as the number of colonies developing per ml. of original water. For estimating this number, all plates containing between 30 and 300 colonies should be taken, the number of colonies multiplied by the reciprocal of the dilution, and the arithmetic mean determined.

In the plates made with the undiluted water it may be found that one of a pair incubated at the same temperature develops less than 30 colonies and the other more than 30, or that in the 1 to 10 dilution one of the plates develops more than 300 colonies and the other less. In either of these cases the mean of the two plates should be taken in estimating the number of colonies per ml. The same applies to plates of 1 in 100 dilution incubated at 20 to 22°C.

If in both plates made from the original water the number of colonies is less than 30, the mean of the two plates should be taken and the results expressed as "approximate only." If in both 37°C. plates (made from the 1 in 10 dilution), or in both 20 to 22°C. plates (made from the 1 in 100 dilution), there are more than 300 colonies, the

^{45a} The Bacteriological Examination of Water Supplies. Repts. on Public Health and Medical Subjects, No. 71 (Revised Edition), 1939, 20-23.

results should be expressed as "more than 3,000 colonies per ml." or "more than 30,000 colonies per ml." respectively.

Direct Methods for Counting Bacteria in Water. The utility of such methods for examination of other foods prompted attempts to develop similar methods for water examination. Nelson ⁴⁶ suggested that the results with direct methods would be higher than those secured with the standard agar plate. He found it necessary to concentrate the bacteria in water before counting them by his method. Zinc hydroxide was used for this purpose; it was dissolved later by ammonium chloride. The bacteria were counted with a Thoma-Zeiss haemocytometer.

Amann ⁴⁷ used a Turk haemocytometer, and made the observation with a dry objective. (D. Zeiss or Seibert IV) and a strong compensation ocular (12 or 18). An electric arc light, a Nernst lamp, or direct sunlight must be used as source of light. Against a black background, the strongly illuminated bacteria may be fairly easily recognized and distinguished from other particles by their form and arrangement, or their motility and translatory motion, which differ from the characteristic Brownian motion of ultra-microscopic particles. A larger number of organisms is found by counting in this way than by the method of gelatin plate culture; thus, a well-water was found to yield only 584 bacterial colonies per ml., whereas the number of organisms found by direct counting was 86,000. One cause of such a difference is the fact that bacteria often occur in aggregations, and an aggregation often gives only one colony, whereas under the ultra-microscope the aggregations are easily perceived and the number of organisms that they contain can be determined approximately. The ultra-microscope method has the advantage of being very expeditious, but on the other hand the bacterial forms cannot be distinguished as in the plate method, and dead cells and sometimes particles are included; moreover, the quantities of water employed in the analysis are too small. Hence the method can only be regarded as a valuable supplement to the usual cultivation method. The Frost "little plate" method was adapted to water analysis and found to yield results which agreed with those secured with the gelatin plate (Eijkmann ⁴⁸).

Indicators of Pollution. As soon as sanitary science had shown that diseases were spread by polluted water and foods, it became necessary to find some method of determining whether a water supply was potentially dangerous. Since chemical methods are not delicate enough, sanitarians have found it necessary to turn to bacteriological methods and indicators. Probably an ideal biological indicator of pollution does not exist and bacteriologists have had to accept those which come the nearest to fulfilling the following requirements as stated by Furphy ⁴⁹ and others before him.

1. It should occur universally and plentifully in human excreta.
2. It should have no other source than the human intestines (owing to the fact that water-borne diseases are entirely those of human origin, the organisms being of intestinal nature and discharged in human feces).

46. Nelson. 1917. J. Amer. Chem. Soc. 39, 515-523.

47. Amann. 1910. Wehnschr. Chem. u. Pharm. 48, 647-665.

48. Eijkmann. 1927. Tijdschr. Hyg. Microbiol. en Serol. 2, 123-131.

49. Furphy. 1925. Australian Commonwealth Dept. Health 3, 168-171.

3. It should live longer in water than the chief water-borne pathogens, but shall die off fairly rapidly.

4. Its occurrence in water should bear a quantitative relation to the pollution received by the water.

5. It should be readily discoverable by simple bacteriological methods.

6. It should have somewhat constant characteristics and not be subject to great change owing to conditions in the environment.

THE STREPTOCOCCI AS INDICATORS OF POLLUTION OF WATER

Presence of many streptococci in the intestinal tracts of animals and man has prompted some bacteriologists to suggest them as indicators of pollution. Since they disappear more rapidly than coliform bacteria during water purification, their presence in filtered water indicates recent pollution. While they have been studied most by British bacteriologists, it is possible that they should receive more attention from Americans. Among the first to seriously study the streptococci as indicators of pollution were Savage and Read⁵⁰ who stated that absence of these bacteria in a water supply is to be considered of less significance than their presence, and even their absence from a considerable bulk of water is not accepted to the same extent as the absence of coliform bacteria, as reliable evidence of freedom from serious contamination. Absence of streptococci is, however, a point in favor of purity. In general, these investigators believed that streptococci in large numbers in a water indicated unsatisfactory source. To test the other matter of longevity which must always be considered, Savage and Wood⁵¹ used strains of streptococci and *Escherichia coli*. At the end of two weeks when *Escherichia coli* was multiplying, streptococci were all dead. Presence of streptococci seemed to indicate to them that the water had been either recently polluted or had received heavy contamination. For this purpose, streptococci may be more valuable than *Escherichia coli*. Hemolytic streptococci in Livingston's⁵² experiments remained alive for varying lengths of time, depending on environmental conditions. Recently isolated strains succumbed quite quickly in water. Houston,⁵³ of the Metropolitan Water Board, was one of the first to attach practical significance to fecal streptococci in water. He studied the streptococcus test for many years and considered it to have merits because streptococci are abundant in human feces, they are absent in fairly large quantities of *pure* water, they do not multiply in *pure* water, and since some are not long-lived in water, their presence might indicate recent pollution. In America, Greer⁵⁴ also looked with favor on the streptococcus test. In a later report⁵⁷ Houston said this test could not compete with the coliform test but could corroborate it as a means of determining excretal pollution. Attempts have been made now and then to differentiate fecal from non-fecal streptococci. Winslow and Hunnewell,⁵⁵ and Fuller

and Armstrong⁵⁶ tried to use the amounts of acid formed in carbohydrate media as a means of such differentiation. Streptococci from human sources formed high acid content in glucose, lactose, and mannite broths and low acidity in raffinose broth. Equine and bovine strains had the opposite abilities.

British practice in water analysis does not recommend search for fecal streptococci as a routine procedure. It is suggested as a supplementary procedure when the results of the coliform test are anomalous. The technic which is recommended is quite like that given below in the Metropolitan Water Board procedures. *Streptococcus fecalis*, considered to be the most characteristic streptococcus in feces, is defined as a "Gram-positive coccus, generally occurring in pairs or short chains, growing in the presence of .5 per cent bile salt, usually capable of development at 45°C., producing acid but not gas in mannitol and lactose, failing to attack raffinose, failing to reduce nitrate to nitrite, producing acid in litmus milk, and precipitating the casein in the form of a loose but solid curd, and exhibiting a greater resistance to heat than most vegetative bacteria."

Houston's Method for Demonstrating Presence of Streptococci in Feces. Drigalski and Conradi plates are inoculated from an emulsion of the feces, made in sterile water. After incubation at 37°C.(98.6°F.), the minute colonies are subcultured in "litmus lemco, lactose peptone" medium. After 24 hours the tubes showing no acidity are discarded; those showing acidity are examined microscopically and if results are satisfactory further subcultures are made into a series of lemco-peptone-sugar media untinted with litmus. After three days incubation at 37°C. the acidity produced is estimated with N/20. NaOH, using phenolphthalein as the indicator. Control tubes are also inoculated. (Mtr. Water Bd. 10th Ann. Report, p. 25, 1914.)

The streptococcus colonies on Drigalski and Conradi plates are small colonies with a tinge of violet. They are to be distinguished from colonies of *Eberthella typhosa* which possess larger colonies.

Detection of Sewage Streptococci. "For this purpose many methods have been devised, but the simplest and best appears to be the examination of the bile-salt glucose broth used for the 'presumptive test' for coliform bacteria. The incubation should, however, be prolonged to 48 hours, and, at the end of that period a loopful from the surface of each tube should be examined in a hanging drop under the microscope. The broth should then be carefully poured off so as to leave at the bottom any precipitate which has been produced. Add a few drops of dilute sodium carbonate solution to dissolve the bile salts and examine again in the hanging drop. If distinct chains are not found, streptococci may be regarded as absent." This method has been found by Thresh to yield the best results.

Savage's Method for Isolation of Streptococcus From Water, Etc. Add .1 and 1 ml. of the sample (water) to tubes of glucose neutral red broth and 10 ml. of the sample to a tube of double strength neutral red broth. Incubate the tubes at 37°C.(98.6°F.) for 48 hours and then examine microscopically in hanging drop for chains of cocci. The broth tube containing the quantity of water next below the one giving a positive result is examined several times in fresh preparations. Where it is doubtful whether chains are present, a little of the fluid is centrifugalized and stained with methylene blue. The streptococci are best isolated from glucose broth tubes by adding a platinum loopful to a litmus lactose plate and distributing over its surface. All suspicious strains must be subcultured and worked out.

Method for Separation of Escherichia coli and Streptococci in Water. "Inoculate the desired quantity of water, preferably 1 ml., into dextrose broth fermentation tube. In-

56. Fuller and Armstrong. 1913. J. Infect. Dis. 13, 142.

cubate at 37°C.(98.6°F.) Examine after six to 12 hours. Within two to three hours after gas formation has appeared, plate the broth into litmus-lactose agar, incubating for 12 to 18 hours at 37°C.(98.6°F.) If, at the end of this time, no acid-producing colonies are present, it is probably safe to assume that there were no colon bacilli present."

After the first plating from dextrose broth, replace the fermentation tube for 36 hours and plate in litmus-lactose agar. This culture should give a nearly pure culture of streptococci, if these organisms were originally present in the water.

Houston's⁶⁷ Method for Determining the Presence of Fecal Streptococci in Water. The procedure starts in the usual manner for determining presence of *Escherichia coli*. One hundred ml. of water are added to 50 ml. of triple-strength lactose peptone bile-salt broth; 10 ml. of water are added to 10 ml. double-strength medium and one ml. to 10 ml. of single-strength medium. The tubes are then placed in water at 37°C. (98.6°F.) for one-half hour and then in the 37°C. incubator. These are *primary* cultures. All tubes showing no visible change after 24 hours are discarded on the presumption that *Escherichia coli* and Streptococci are absent. Those in which gas formation occurs are subcultured in the following manner: After shaking, from two to four drops are spread over the bottom of a sterile Petri dish. The dish, with lid raised, is then placed in a dry 37°C. incubator for about 15 minutes to dry the liquid onto the glass; it is then placed in a moist 37°C. incubator with 85 per cent humidity for 45 minutes. After such treatment from 30 to 40 ml. of melted agar are poured over the culture and the dish gently rotated. The plates are then incubated for 24 hours at 37°C. After incubation the agar is removed with a sterile spatula and the colonies on the underside are cultured in lactose-lemco-peptone-litmus broth and on a fresh agar slant containing .1 per cent sodium nitrate. These should be incubated at 37°C. for 24 hours. Acid without gas in lactose broth, presence of chains on the agar slant, and absence of reduction of nitrates to nitrites indicate presence of fecal streptococci.

This technic was slightly modified in the report for 1931. The purpose in drying the culture as outlined above was to eliminate most of the *Escherichia coli*. In the new modification, one ml. of the culture was added to 10 ml. sterile water and the mixture heated to 60°C.(140°F.). After some 10 to 20 minutes a few drops of the mixture were spread over Drigalski and Conradi medium in plates. It was stated that ordinary agar could be used if less of the liquid were used for inoculation. After the plates had been incubated for 24 hours the colonies were subcultured as described above.

The Metropolitan Water Board Method for Determining Presence of Fecal Streptococci in Water. This method would, of course, be quite similar to the one just quoted from Houston.

The Metropolitan Water Board of London in its 31st annual report (1936) proposed two methods for the isolation of streptococci in water, as follows:

The first, or "drying method," essentially that credited to Houston above, entails somewhat lengthy manipulation, provides many opportunities for contamination, and is not often employed.

The second method, commonly used, depends upon the bile insoluble and heat-resistant properties of the fecal streptococcus, which permits utilization of the positive lactose MacConkey broths of the test for coliform bacteria as a dual enrichment medium. Briefly, the procedure is to heat a small quantity of fluid from a presumptive tube in the coliform test to 60°C.(140°F.) for 15 to 20 minutes and plate a loopful of the suspension on Conradi-Drigalski medium. Positive results were generally obtainable with samples of raw Thames water in the 10-ml. and one-ml. amounts, but the recovery of the streptococcus is less successful from the 100-ml. amounts, where a larger variety of other organisms are present in competition. On such occasions, plates are crowded with Gram-negative bacilli, which have heat-resisting powers similar to the fecal streptococcus.

The following year results of a comparison of the coliform test with the streptococcus test by examining MacConkey tubes giving acid or acid and gas were reported. Three methods were used: the heating method and the direct tellurite and enrichment

tellurite methods which are described below. The resulting colonies were confirmed. It was pointed out that *Streptococcus fecalis* was resistant to a temperature of 60°C. (140°F.) for 30 minutes.

(a) *Direct plating method.* This consisted of the subculture of fluid from unheated presumptive tubes on the surface of an agar medium containing potassium tellurite of the composition:

Agar, 2 per cent
Lactose, .5 per cent
Peptone, 1 per cent
Di-potassium hydrogen phosphate (anhydrous), .2 per cent
Sodium chloride, .5 per cent
Potassium tellurite, 1 in 15,000 added as sterile solution.

Plates were poured, dried for one to two hours, spread with one drop of fluid from the MacConkey broths and incubated at 37°C. (98.6°F.) for 24 hours. *Streptococcus fecalis* appeared as small bluish-black colonies about one mm. in diameter, with opalescence of the periphery.

The organisms were characterized by the production of acid, without gas, a deposit in lactose "lemco" medium, the non-reduction of nitrates under aerobic conditions and morphologically.

The results obtained were closely comparable to the heating method with the added advantage of ease of manipulation. However, occasionally other tellurite resistant organisms were found, which persisted in concentrations of one in 5,000. Some provided coliform reactions.

(b) *Enrichment method.* Two drops of the contents of a positive McConkey tube were used as an inoculum into a fluid medium, having the following composition:

Peptone, .5 per cent
Lactose, .5 per cent
Di-potassium hydrogen phosphate (anhydrous), .5 per cent.
Potassium tellurite, 1 in 15,000.

After incubation for 24 hours at 37°C., single colonies were obtained by placing on lactose tellurite agar as described above.

This method gave better results than the direct plating method, the preliminary enrichment leading to the elimination of resistant coliform and other organisms which, at times, overcrowded the plates during heating and direct tellurite techniques.

As already stated, the isolation of *Streptococcus fecalis* supports the *Escherichia coli* test and, generally speaking, the organisms are 10 times less prevalent than coliforms; but with excessive pollutions failures of recovery are frequent, owing to competition with the other organisms and to the presence of particularly resistant types, the characters of which are being investigated.

Since the tellurite methods outlined do not include a heating process, the possibility arises that certain of the streptococcal types isolated may not prove to be heat-resistant and therefore should not be termed *Streptococcus fecalis*. Yet, presumably these organisms are of human or animal origin and therefore their presence must have some significance. Furthermore, long experience with heating methods up to 60°C. proves that this is associated with considerable mortality of *Streptococcus fecalis*.

Nevertheless, after extensive trials, the tellurite enrichment method of streptococcal isolation has proved itself far superior to the original drying or heating techniques, and its use is to be strongly recommended.

Eberthella typhosa and *Salmonella* strains were found by Fleming and Young⁵⁸ to be very sensitive to the inhibitory action of potassium tellurite in agar medium or in broth. Growth was suppressed in concentrations as low as one to one million. Dysentery bacilli are almost as sensitive. *Pseudomonas aeruginosa* (*Bacillus pyocyaneus*) is inhibited by one in 100,000 tellurite. Many strains of *Proteus vulgaris* and some *Escherichia coli* will

grow in concentrations of one in 100,000. Resistant and sensitive strains of *Escherichia coli* or *Proteus vulgaris* do not differ in their fermentative or antigenic characters. Insensitive bacteria absorb tellurite from the culture medium and so allow growth of sensitive bacteria in the neighborhood. Bacteria can be readily acclimatized to tellurite. Use of tellurite to facilitate the isolation of Gram-positive cocci from feces, septic wounds, or other material is indicated.

A new medium for fecal streptococci was reported by Hajna and Perry (1942) at the St. Louis convention of the American Public Health Association. Sodium azide was the inhibiting agent for Gram-negative bacteria with temperature selection at 45.5°C. Mere presence of acid and growth is confirmatory evidence of presence of fecal streptococci. The medium may be inoculated directly with water, milk, or sewage.

ANAEROBIC BACTERIA AS INDICATORS OF POLLUTION IN WATER AND FOODS

Anaerobic bacteria in water have received much less attention than aerobic species. Believing that a large number of anaerobes indicated active organic decomposition and fecal pollution, Vincent⁵⁹ suggested their enumeration as an index of pollution. Satisfactory waters were said to contain one to two anaerobes, or less, per ml. Waters containing more were regarded as progressively unsatisfactory. Meader and Bliss⁶⁰ found anaerobic bacteria in water responsible for gas formation in the presumptive test in water analysis. In pure culture the anaerobes formed no gas from lactose, which led Meader and Bliss to believe that a symbiotic condition existed, as was later shown to be the case by Holman and Meekison.⁶¹ Horovitz⁶² identified a number of anaerobic bacteria from water which had been treated with ozone. Such forms would be among those which would survive any effort to reduce the general flora. This would affect their use as indicators of pollution.

Clostridium sporogenes was discovered by Klein in 1895 in diarrhea stools. Its use as an indicator of pollution rests on the fact that it is present in feces and, therefore, in sewage. This organism should be regarded as one of a group of bacteria the members of which are very closely related. *Clostridium welchii* is probably identical with Klein's *Bacillus enteritidis sporogenes*. Welch described his bacillus as nonmotile but otherwise the descriptions and the changes produced in milk are identical. The nomenclature of this group is confused. Examination of water for this organism may require concentration either by filtration or evaporation under reduced pressure at low temperatures. Decimal dilutions of this concentrated sample should be made and one-ml. quantities added to sterile litmus milk. It is a good plan to boil the tubes of milk for five

or 10 minutes before inoculating in order to expel as much air as possible. After the tubes have been inoculated they should be heated on a water bath at 80°C. (176°F.) for 20 minutes to kill vegetative forms. They are then incubated under anaerobic conditions, made anaerobic by the Wright method. If anaerobes are present a "stormy fermentation" results. It is characterized by separation of curd from the whey and violent gas formation. A quite similar test has also been proposed for demonstrating anaerobic bacteria in milk.

Clostridium welchii has at times assumed some importance in water analysis; it has been suggested as the cause of severe outbreaks of enteritis. Larner⁶³ suggested a probable relation of *Clostridium welchii* to intestinal disturbances among those who drank polluted water. In some cases, the symptoms disappeared when the patients drank boiled water. Meader and Bliss⁶⁰ did not find *Clostridium welchii* in water. The question of its sanitary significance is further complicated by the fact that *Clostridium welchii* is said to serve useful ends in the preparation of certain foods. Koser, for instance, found it as the leavening agent in a starter for self-rising bread, while Albus⁶⁴ reported it as the cause of gassy fermentation in Niszler cheese. Such reports complicate its use as an indicator of pollution. Wilson and Blair⁶⁵ prepared a special sulfite-glucose-iron agar medium for determining *Clostridium welchii* in water and observed a close correlation between the results of the *Escherichia coli* and *Clostridium welchii* tests. The latter was believed to be a good supplement to the former. In an investigation of the significance of lactose-fermenting bacteria in water by Greer, Noble, and Tonney⁶⁶ *Clostridium welchii* was suggested as of less value as an indicator of pollution than *Escherichia coli*. Sudden increase in the number of *Clostridium welchii* and other lactose fermenters in Lake Michigan water when the ice breaks up, was attributed by Gorman, Greer, and Hlavacek⁶⁷ to filling material along the lake front. Such a situation would lead to a greater incidence of false presumptive tests for *Escherichia coli*. Anaerobic sporeforming bacteria would also be resistant to water-treatment methods. That *Clostridium welchii* is present in large numbers in soil was shown by Skinner and Baskin.⁶⁸ Contrary to the experience just discussed, Lewis, Green, and Hamilton⁶⁹ found no merits in the *Clostridium welchii* test for water. The results of this test did not correlate with those of the *Escherichia coli* test. A similar opinion was reached by Matheson⁷⁰ in a sanitary survey of Burlington Bay and Lake Ontario. Definite correlation of results with the *Escherichia coli* test with those from use of sulfite-glucose-iron agar were not satisfactory. This latter medium had been suggested by Adams⁷¹

as especially suitable for enumerating anaerobic bacteria in water. He favored the use of anaerobes as indices of pollution.

Larner's⁷² Method for Showing the Presence of *Clostridium welchii* (*Bacillus welchi*) in Water. In making the *Clostridium welchii* test at the Montclair Board of Health laboratory 10-ml. samples of water are inoculated into each of five fermentation tubes containing lactose peptone broth. The tubes are incubated at 37.5°C. (99°F.) for 72 hours. From tubes showing the production of gas in amounts varying from 40 to 100 per cent, and having a typical butyric acid odor, a loopful of medium is placed in a Petri dish and an Endo plate poured (not smeared) about one-fourth inch thick. The plates are incubated at 37.5°C. (99°F.) for 24 hours. A typical red colony showing a bubble of gas at the bottom of the dish is then fished and inoculated into a tube containing five ml. of sterile whole milk which has been recently boiled to drive off absorbed oxygen. Hot sterile paraffin is next poured on top of the milk so that when cool it forms a solid air-tight seal about one-half inch thick with the production of anaerobic conditions. The tube is then incubated 24 hours at 37.5°C. (99°F.). Coagulation of milk with typical stormy fermentation and gas production, which forces the paraffin seal to the top of the tube, is taken as confirmatory evidence of the presence of *Clostridium welchii*.

Jackson and Muer's⁷³ Method for Showing Presence of *Clostridium welchii* in Water. 1. Inoculate various dilutions (usually .1, 1, and 10 ml.) of the water or milk to be tested into fermentation tubes containing liver broth, and incubate for 24 hours at 37°C. (98.6°F.). If *Clostridium sporogenes* is present either in the spore or vegetative state in the dilutions used, there will be gas formation, accompanied by an offensive cheesy odor, and microscopic examination will show numerous and vigorous spores. *Clostridium welchii* in liver broth gives no odor and no spores, but an abnormal amount of gas. By observing in which dilutions they are present, the relative degree of contamination of these bacteria will be apparent. Numerous bacteria, both vegetative and sporeforming, have been examined but none have been found that give this strong peculiar odor in liver broth except *Clostridium sporogenes*. This is the presumptive test for the presence of *Clostridium sporogenes*. Large rounded bacilli with heavy gas formation, no spores, and no odor is the presumptive test for *Clostridium welchii*.

2. To complete the test for *Clostridium sporogenes* and isolate a pure culture of the organism, transfer the entire contents of each tube showing gas plus characteristic odor into separate sterile Erlenmeyer flasks or large test tubes and heat to 80°C. (176°F.) for 10 minutes. Any attenuated spores or vegetative bacteria present in the original samples will have formed vigorous spores, and the heating destroys all species of vegetative bacteria that might interfere with its further separation.

3. One ml. or less of broth containing sediment may be withdrawn from the bottom of the flasks or tubes after heating and planted separately into a second set of sterile liver broth fermentation tubes and incubated for 24 hours at 37°C., after which time gas formation and characteristic odor will again be observed. Microscopic examination will reveal the presence of numerous large sluggishly motile bacilli containing spores. Often *Clostridium sporogenes* is now present in pure culture.

A stab culture made from this 24-hour liver broth culture into dextrose liver gelatin, will demonstrate the presence of *Clostridium sporogenes* by its characteristic growth. Within 48 hours after incubation at 20°C. (68°F.) a distinct anaerobic growth will be observed, beginning about two ml. below the surface. Liquefaction will be well advanced and gas bubbles will accumulate at the top of the liquefied area.

4. To obtain colonies of *Clostridium sporogenes* on agar plates it is necessary to transplant a few drops of broth and sediment from the second set of fermentation tubes, in step 3, into a third set of tubes and incubate for three to five hours at 37°C. After that period a distinct anaerobic growth will be observed in the closed arm, and a few bubbles of gas will be found at the top. The *Clostridium sporogenes* is now in the vegetative state and this is the only condition in which it will grow on the plates.

72. Larner. 1922. J. Amer. Med. Assoc. 78, 276-279.

73. Jackson and Muer. 1911. J. Infect. Dis. 8, 289-294.

The contents of the closed arm are transferred to the bulb by tilting forward and plating in dilutions of 1 to .00001 ml. on dextrose liver agar, and incubating for 12 to 18 hours in hydrogen at 37°C.(98.6°F.). Typical colonies will then be visible, consisting of one or more gas bubbles surrounded by a delicate white fringe. The plate cultures also will have a disagreeable cheesy odor.

5. From one of these colonies a deep stab culture is made into dextrose liver agar and incubated for 24 hours at 37°C.(98.6°F.). A distinct anaerobic growth will be observed along the line of puncture, and sometimes the agar is split into two or three layers by the gas evolved. A liver gelatin tube inoculated and incubated at 20°C.(68°F.) will also give a very distinctive anaerobic growth.

6. A subculture may also be made into litmus milk and incubated for 48 hours, anaerobically, after which time there will be a complete separation of curd and whey and a strong odor of butyric acid. Sometimes the curd adheres to the sides of the tubes and has a peculiar shredded appearance.

Many other types of sporeforming bacteria may be isolated by this method. By this procedure Jackson and Muer several times isolated large numbers of *Bacillus vulgaris* and other similar species from condensed milk which caused diarrheal disturbances. As *Clostridium welchii* does not form spores in liver broth it must be isolated direct from the liver broth without heating.

Metropolitan Water Board Procedure⁷⁴ for Estimating *Clostridium Welchii* in Waters. A test was described in the Thirty-third Annual Report as follows:

Reagents Required:

- a) 20 per cent solution of anhydrous sodium sulphite
- b) 8 per cent solution of ferrous sulphate
- c) glucose agar (1 per cent glucose and 3 per cent agar)

Two milliliters of solution (a) are introduced into a large sterile Petri dish (4½ in. diam.) and a suitable volume (10 ml., 1 ml., etc. according to the expected degree of pollution) of the sample, which has previously been heated to 80°C.(176°F.) for 10 minutes, and .2 ml. of solution (b) in 10 ml. of sterile distilled water are then added, and the plate poured with the agar mixture (c) and thoroughly mixed. Finally, when the plates are cool and the agar has solidified, a thin layer of the same agar mixture is poured over the surface to produce somewhat anaerobic conditions.

Plates are then incubated at 44°C.(111.2°F.) for 24 hours following the method of Wilson *et al.* (1935). This temperature obviates the necessity for a special incubator and it has been found as efficient as the higher temperature for inhibition of *Bacterium effluvii* and other saprophytic organisms.

The appearance of black colonies three millimeters or more in diameter is highly significant of the presence of *Clostridium welchii* and justifies the presumption that fecal pollution of recent or remote origin has taken place. The test, however, was said to be insufficiently delicate for use with natural water when the standard of purity is *Escherichia coli* absent in 100 ml. It was believed that the test might be of use with supplies such as surface wells which were intermediary polluted.

The bacteriological laboratory of the Metropolitan Water Board of London has also studied the significance of *Clostridium welchii* in water. According to their results the *Clostridium welchii* test does not follow the coliform index quite as closely as does the fecal streptococcus test. Improved results, however, were secured by heating samples for Wilson's test at 80°C.(176°F.) for 10 minutes with subsequent incubation at 45°C.(113°F.). This eliminates *Bacillus effluvii* in the summer. Testing of large or medium colonies from Wilson's plates in milk gave only 78.6 per cent positive stormy fermentation. Heating of the samples to 80°C.(176°F.) and incubation in litmus milk at 37°C.(98.6°F.) gave the best results on the whole. Under these conditions both methods correlated better with the coliform and streptococcus tests.

In the thirty-third annual report for the year 1938 the Metropolitan Water Board reported more data on the *Clostridium welchii* test. Incuba-

74. Thirtieth Ann. Rept., Metropolitan Water Bd., London, 1935, p. 10; also 33rd Ann. Rept. 1938.

tion at 45°C.(113°F.) did not completely inhibit them. Since 1935 it has been the practice of these laboratories to heat the sample to 80°C.(176°F.) for 10 minutes previous to inoculation in order to destroy nonsporeforming bacteria so that the test became an estimation of organisms of the anaerobic-sporeforming group. Other media for cultivation of streptococci from water have been proposed by Folpmers.⁷⁵

British standard practice^{45a} of water examination apparently does not provide for demonstrating presence of *Clostridium welchii* in potable water. Two methods are given, however, for this purpose, a litmus-milk method and a sulfite-reduction method.

THE COLIFORM GROUP AS INDICATORS OF POLLUTION

Presence and estimation of the number of coliform bacteria in water has become an integral part of the bacteriological procedure for judging quality. The most direct and satisfactory procedure would be to plate the water on a medium which would permit direct enumeration for coliform bacteria. Despite development of several media for this purpose, they have not generally been viewed with approval by those who prepare standard methods. Some of the difficulties with such media are quite apparent and have, in general, been reviewed a few pages further on in this chapter. They involve the necessity of proving that each colony which appears to be *Escherichia coli* is really such a colony.

Standard Methods of Water Analysis, eighth edition, 1936, recommended that the coliform group be considered as including all aerobic and facultative, anaerobic, Gram-negative, nonsporeforming bacilli which ferment lactose with gas formation. This group has been referred to in sanitary literature as the coli-aerogenes group. Breed and Norton,⁷⁶ however, suggested introduction of the term *coliform* to designate lactose-fermenting, aerobic bacteria used as a measure of pollution in water. They hoped that the term would be used in milk and oyster contamination with similar meaning, which seems to have been done.

The generally accepted procedure today involves use of liquid media and dilutions of the water sample to show not only presence of coliform bacteria but to yield information about their probable numbers and types. Procedures for determining probable numbers from dilutions in liquid media are discussed later in this chapter.

The procedures used in sanitary work are not fixed. The marked changes which are made in standard procedures by every committee indicate the difficulties involved.

Escherich isolated *Escherichia coli* soon after discovery of solid media by Koch. He was attempting to find the causal organism of cholera. At first he thought that he had found it because *Escherichia coli* was found in the intestinal tract of each patient. Later investigations indicated that it was always present in the feces, and from these facts bacteriologists attempted to use it as an indicator of the presence of fecal matter in

foods and beverages. For some time it was accepted as a reliable indicator, but as knowledge increased it became apparent that some limitations had to be placed on the test. Much of our work since this time has been concerned with finding out what these limitations are.

The value of the *Escherichia coli* test was attacked by some practical waterworks operators. They argued from the several researches which had shown that the organism may not at all times be restricted to sources which have received sewage pollution. Rogers, Clark, and Evans,⁷⁷ Prescott,⁷⁸ Metcalf,⁷⁹ Smith,⁸⁰ and others reported the isolation of the organism, or *Escherichia coli*-like organisms, from grain fields and grains which had not received sewage pollution. Their work was of such import that it was believed necessary to differentiate fecal from non-fecal *Escherichia coli*. The English and American bacteriologists have regarded the *Escherichia coli* test with favor while some German bacteriologists have objected to it. Kruse,⁸¹ for instance, believed that *Escherichia coli* could be found in any water, no matter from what source, provided a large enough sample is examined. Chick,⁸² on the other hand, believed that *Escherichia coli* is not present in water unless it has received sewage pollution. Race⁸³ believed that *Escherichia coli* was a reliable indicator of pollution and stated that those cities which have many *Escherichia coli* in their water usually have a high typhoid fever death rate. He warned that *Escherichia coli* should not be considered merely an inferential indicator. The fact that its presence in a sample of water may not be sufficient evidence of serious pollution does not mean that the organism may be safely overlooked. Houston⁸⁴ considered *Escherichia coli* to be the best index for control of water purification process. Winslow,⁸⁵ in tracing the history of this organism as an indicator, advised accumulation of as much data as possible to determine more definitely whether *Escherichia coli* is purely a fecal form and *Aerobacter aerogenes* a saprophytic form. Thus supposition has involved differentiation of *Escherichia coli* from *Aerobacter aerogenes*. The methods for doing this are given below. Before this differentiation was done, bacteriologists had probably used the term *Escherichia coli* as a collective one, including many lactose-fermenting bacteria with characteristics in common but differentiable when certain other tests were applied. Bacteriologists were soon convinced that the mere presence of bacteria which formed acid and gas from lactose could not be accepted as evidence of fecal pollution. Acid and gas may result from the activities of other bacteria which are devoid of sanitary significance. This made it imperative to study the lactose fermenters from sources, pollution of which was beyond question, and from sources which were satisfactory as far as could be determined by careful examination.

Rogers and his colleagues instituted investigations to determine whether coliform bacteria from polluted sources differed in any way from those from unpolluted sources. The results of these investigations were published by Rogers, Clark, and Davis⁸⁶; Rogers, Clark, and Evans⁸⁷; and Rogers, Clark, and Lubs.⁸⁸ Their investigations showed that coliform bacteria could be divided into two groups on the basis of the amount of carbon dioxide and hydrogen formed—spoken of as the gas ratio. The subgroup peculiar to the bovine intestinal tract was characterized by a relatively low gas ratio of one part of carbon dioxide to 1.06 parts of hydrogen. These strains from the bovine intestinal tract also differed a little in other characteristics. A series of strains from grains gave a high gas ratio between 1.9 and 2.2. The former are known as *Escherichia coli* and the latter as *Aerobacter aerogenes*. The gas ratio, under very carefully controlled conditions, functions as a means for distinguishing between lactose-fermenting bacteria from polluted sources and those from unpolluted sources. It is not suitable for routine analysis.

The next important step was to show that the electrometric determination of hydrogen-ion concentration could also be used for distinguishing between the two subgroups. The fecal type (*Escherichia coli*) had a higher hydrogen-ion concentration than did the grain type (*Aerobacter aerogenes*). The electrometric determination of hydrogen-ion concentration is not suited to routine analytical work, and therefore cannot be used.

Clark and Lubs⁸⁹ found that under certain conditions methyl red could be used for distinguishing between the hydrogen-ion concentrations of the two subgroups. They reported that this test correlated perfectly with the gas ratio. Clark⁹⁰ found remarkable agreement in the final hydrogen-ion concentrations of different strains of *Escherichia coli*.

While such a distinction between these two closely related bacteria was a part of water analysis for several years, it seems to have lost its significance in recent years. The cleavage on the basis of source, that *Escherichia coli* meant fecal pollution, and *Aerobacter aerogenes* was of no sanitary significance, is now considered to be of little value. This change in opinion has been due, in part, to presence of *Aerobacter aerogenes* in materials which were known to be polluted.

Standard Methods of Water Analysis, eighth edition, 1936, states that the standard tests for the coli-aerogenes groups shall be either of the following:

A. *Presumptive Test*. Formation of gas in a standard lactose broth fermentation tube at any time within 24 hours with incubation at 37°C., or formation of gas during a second 24-hour period with confirmation as described below, is presumptive evidence of presence of members of the coliform group.

86. Rogers, Clark, and Davis. 1914. *J. Infect. Dis.* 14, 411-475.

87. Rogers, Clark, and Evans. 1914. *Idem* 15, 99-123.

88. Rogers, Clark, and Lubs. 1916. *J. Bact.* 1, 82; 3 (1918), 231-251.

89. Clark and Lubs. 1915. *J. Infect. Diseases* 17, 160.

90. Clark. 1915. *J. Biol. Chem.* 22, 87-98.

B. *Confirmed Test*. Formation of gas at any time within 48 hours with incubation at 37°C. in a fermentation tube containing a specified liquid confirmatory medium which has been seeded from a lactose broth fermentation tube in which gas has been formed (in the presumptive test), or appearance of lactose splitting colonies on a specified solid confirmatory medium, confirms the presumption that gas in the presumptive test resulted from presence of members of the coliform group.

C. *Completed Test*. To complete proof that gas resulted from an organism in the coli-aerogenes group, it is necessary to show that one or more aerobic plate colonies consist of Gram-negative, nonsporeforming bacilli which form gas in lactose broth.

THE PRESUMPTIVE TEST FOR PRESENCE OF COLIFORM BACTERIA

The ability of bacteria, other than *Escherichia coli*, to form acid and gas from media used in the presumptive test in water analysis, has made it necessary to consider this acid and gas as presumptive evidence only of the presence of coliform bacteria. It is necessary to continue observations to prove that coliform bacteria of sanitary significance are the source of the gas and acid observed in the presumptive test.

The Presumptive Test Medium. Various media have been used in the presumptive test. Dextrose broth was once recommended by *Standard Methods of Water Analysis* of the American Public Health Association. Lactose broth was finally substituted and has been in use since. British sanitary bacteriologists have used MacConkey's⁹¹ broth because they believe it reduces false presumptive tests to a minimum, owing to the bile salt contained in it. They further believe that lactose broth recommended in American practice does not do this but yields positive presumptive tests which will not confirm.

Lactose broth, the standard medium, has been compared with various other media on different occasions, and has, in general, been found to be about as good. Darby and Mallmann⁹² stated that tryptose was superior to peptone in the base medium for coliform bacteria. A concentration of two per cent yielded best results. The concentration of lactose seemed to be less important.

From time to time substances have been added to lactose broth to make it better by either suppressing development of other organisms which may give spurious positive tests or by favoring development of fecal *Escherichia coli*. Some of them are discussed below. Several comprehensive comparative studies with different media have revealed that standard lactose broth is about as satisfactory as many of its modifications. Horwood and Heifetz⁹³ recommended its retention although brilliant green lactose bile did show considerable promise.

A. PRESUMPTIVE TEST

The presumptive test indicates the presence only of bacteria which form acid and gas from lactose. They may be coliform bacteria or other bacteria of no sanitary significance. The eighth edition (1936) of *Standard Methods of Water Analysis* defines the presumptive test as formation of gas in standard lactose broth at any time within 24 hours at 37°C., or its formation during a second 24-hour period with confirmation.

American Public Health Association Method of Testing for Presence of Members of Coli-Aerogenes Group. It is recommended that the *Escherichia coli* group be considered as including all nonsporeforming bacilli which ferment lactose with gas formation and grow aerobically on standard solid media.

1. Inoculate a series of lactose broth fermentation tubes with appropriate graduated quantities of the water to be tested. Each fermentation tube must contain at least twice as much medium as the portion of sample to be tested, or the concentration of peptone and lactose in the mixture of medium and added portion of sample must conform to the requirements given under Part VII, Sec. III, N, 2. The portions of the water sample used for inoculating the lactose broth fermentation tubes will necessarily vary in size with the character of the water under examination. (This refers to instructions concerning strength of media. Where large quantities of water are examined, stronger media should be used to compensate for dilution—Author.)

2. Incubate the fermentation tubes at 37°C. for 48 hours unless gas appears earlier. Examine each tube at the end of 24 hours, and if no gas then appears again at the end of 48 hours. Record presence or absence of gas formation at each examination of the tubes.

More detailed records of the amount of gas formed, though desirable for the purpose of study, are not necessary for carrying out the standard tests prescribed.

3. Formation within 24 hours of gas in the inverted vial in the fermentation tube constitutes a *positive presumptive test*.

4. If no gas or only a small bubble of gas is formed in 24 hours, the incubation shall be continued to 48 hours. If gas in any quantity is present after the second but not the first 24-hour incubation period, the test is considered as doubtful and the presence of organisms of the coli-aerogenes group should be confirmed. Confirmed tubes may then be given the same consideration in the presumptive test as those showing gas formation in the first 24-hour incubation period.

5. The absence of gas formation after 48 hours' incubation constitutes a negative test. (An arbitrary limit of 48 hours' observation doubtless excludes from consideration occasional members of the coli-aerogenes group which form gas very slowly. For the purpose of a standard test the exclusion of these occasional slow gas-forming organisms is considered immaterial. (From *Standard Methods of Water Analysis*, 8th Edition, pp. 211-212.)

According to Levine, the *positive presumptive test* is a reliable index to the probable presence of *Escherichia coli* when dealing with untreated waters but is not to be depended upon for chlorinated waters. The *doubtful presumptive test* is found to be only a fair index of the probable presence of *Escherichia coli* in untreated waters, while it is practically of no value for treated waters. The amount of gas has little significance. The rate of gas formation is said to be more significant.

Many reasons exist for spurious presumptive tests. A few are discussed below.

1. *Presence of other lactose-fermenting bacteria of doubtful or no sanitary significance.* Several such bacteria exist. Some of them are quite widely distributed and may cause trouble in water analysis. Certain

Streptococci, members of the proteus group, and *Bacterium capsulatum* are examples. The most significant bacterium in this category is probably *Bacillus asteroporous* (Meyer), an organism having all the characteristics of *Escherichia coli* with exception that it forms spores. It appears in soil, for Bredemann⁹⁵ found it in soils from various parts of the world. It has also been found by Gottheil,⁹⁶ Ankersmit,⁹⁷ Behrens,⁹⁸ Aderhold,⁹⁹ Meyer,¹⁰⁰ and Ewing.¹⁰¹

Bacillus asteroporous has been shown by different investigators to cause spurious presumptive tests in water analysis as well as in analysis of other foods. Hinman and Levine¹⁰² reported this organism to be in Iowa surface water. More recently it has been isolated from other water supplies.

Sohn¹⁰³ reported the presence of sporeforming, lactose-fermenting bacteria in 21 of 99 samples of Ohio river water. Of these 18 were capable of growing aerobically and 16 anaerobically. Only six of the 21 cultures survived plating and purification. During this period 85 per cent of positive presumptive tests were confirmed. Berry¹⁰⁴ found a sporeforming, lactose-fermenting organism in the water supply of Akron, Ohio. Ginter,¹⁰⁵ at Tulsa, Oklahoma, reported that 27 per cent of samples of chlorinated water gave positive results which would not confirm. These were due to an organism similar to the one described by Norton and Weight.¹⁰⁶ He reported that neither 17 p.p.m. of chlorine nor 19 p.p.m. of copper (in terms of metallic copper) killed the organism. A sporeforming, lactose-fermenting bacterium was also found by Calvert¹⁰⁷ in the Indianapolis water supply in the winter months only. Greer¹⁰⁸ reported a lactose-fermenting, aerobic, sporeforming bacterium which was believed to be sufficiently different to justify a new name. The name *Bacillus aerosporous* was proposed by Norton, who had observed the organism before.

These species were studied by Porter, McCleskey, and Levine.¹⁰⁹ Included in their investigation were all of the available organisms of this group, e.g., the original strains of A. Meyer, Bredemann, Wagner, Schar-dinger, and Northrop. The cultures studied fell into two distinct species, *Asterosporous polymyxa* and *Asterosporous macerans*. Hupp¹¹⁰ stated that these forms could be suppressed by adding sodium lauryl sulfate to the broth.

2. *Anaerobic bacteria.* Besides the aerobic bacteria just discussed there are numerous anaerobic forms which may cause much confusion in the presumptive test. *Clostridium welchii* is a good example. Greer¹⁰⁸ and Spray and Laux¹¹¹ found anaerobic bacteria to be causes of lactose fermentation in presumptive tests which could not be confirmed. Kahn¹¹² stated that differentiation between *Escherichia coli* and anaerobic lactose fermenters was accomplished on Endo's medium when it is incubated aerobically. He used Endo's medium slants instead of plates. Anaerobes are able to develop in the lower reaches of the fermentation tube even though no attempt is made to create anaerobic conditions. Skinner and Baskin¹¹³ found by one method from six to 5,699 anaerobes in a gram of soil and with another method, two to 10,000. They concluded that these organisms could not be of sanitary significance in water examination. Anaerobic bacteria have been found in well water by Bohdanowicz and Piotrowska¹¹⁴ using Wilson and Blair's medium. No relation between the *Escherichia coli*-index or the number of aerobic bacteria and the number of anaerobic bacteria was observed. The presence of anaerobes usually indicated extreme pollution where *Bacillus perfringens* showed that pollution was pathogenic and of long standing. Atkinson and Wood¹¹⁵ observed that false presumptive tests might be due to presence of anaerobic bacteria of the *Clostridium welchii* group in association with a member of the *Proteus* group.

3. *Presence of lactose-fermenting yeasts.* Lactose-fermenting yeasts are by no means uncommon in nature and might occasionally cause trouble in the presumptive test. They are encountered frequently in the dairy industry, where they bring about very active fermentation.

4. *Production of a lethal hydrogen-ion concentration during preliminary enrichment.* This possibility was proposed by Thompson¹¹⁶ who investigated true positive presumptive tests which failed to confirm. In order to avoid this difficulty he prepared standard lactose broth buffered with dipotassium phosphate. Janzig and Montank¹¹⁷ reported that the use of lactose broth with a decreased hydrogen-ion concentration resulted in the elimination of 47 per cent of false presumptive tests. This reduction allowed a great saving in time and materials.

5. *Presence of bacteria with all of the characteristics of Escherichia coli (Bacterium coli) but originating probably from unpolluted sources.* Reinke¹¹⁸ found that samples of water collected from well pumps in Chicago were frequently contaminated with bacteria which could not be differentiated from *Escherichia coli* by any of the ordinary methods. It was found that these bacteria were coming from pump leathers, replacement of which caused the bacteria to disappear from the water. Greer,¹¹⁹

119. Greer. 1928. Engin. News-Rec. 101, 407.

and Greer and Kells¹²⁰ described this organism under the name of "The Leather Bacillus." This organism was confirmed as *Escherichia coli* (*Bacterium coli*). Washers from a pump were found to be impregnated with it. The first washer had been kept in the laboratory for nine months when the report was made and was still giving off great numbers of cells. Organisms from such a source could hardly be considered of sanitary significance. Frantsev¹²¹ found that *Escherichia coli* could grow abundantly on lubricating grease in stuffing boxes of water pumps. Parr¹²² believed that such bacteria might vary from the true type. However, if they enter the water they give evidence of pollution and must be considered.

Fish and amphibians may also seed water with *Escherichia coli*. Johnson¹²³ pointed out that the colon organisms could multiply in the intestinal tract of fish and that the fish migrating from polluted water might seed unpolluted water with *Escherichia coli*. While *Eberthella typhosa* might also be carried, it is still pertinent to wonder what effect such observations should have on interpretation of results of water analysis. Another animal which might play a similar role is the salamander. Kline and Fuller¹²⁴ showed that they continue to shed large numbers of *Escherichia coli* into water after they have fed on food containing these microorganisms. Similar observations were reported by Hassler.¹²⁵

These creatures occur, often in large numbers, in springs and streams throughout the country. One hundred salamanders were collected from different springs by Hassler, placed in sterilized cans, and taken to the laboratory where they were autopsied and bacteriological examinations made of portions of their gastrointestinal tracts. A small percentage were found to contain typical coliform bacteria, when little or no food was found in the alimentary tracts. Additional tests, made on the large purple salamanders, indicated how they might infect a spring. Tests showed that over a period of 122 days one salamander excreted a sufficient number of coliform bacilli per day to contaminate 237 gallons of water heavily enough to be considered dangerous on every test. It is believed that they act as reservoirs or incubators and, having once been infected with coliform bacteria, continue to excrete them as long as there is food in the salamander's stomach or intestines to supply nourishment to the bacteria. Bacteriological examination of water in which salamanders were living might result in condemnation even though the supply was otherwise unpolluted. The question is whether pathogenic bacteria might be carried in this manner. Houser¹²⁶ mentioned pollution of reservoirs by sea gulls and other birds. Houston¹²⁷ found no *Eberthella typhosa* in droppings of sea gulls but did find *Escherichia coli*. Adams¹²⁸ also confirmed this.

128. Adams. 1933. *Penn. Water Wks. Operators Assoc.* 5, 12-13.

6. *Overgrowing of Escherichia coli by other bacteria.* This was referred to as "masked positive" by Atkinson and Wood.¹¹⁵ Coliform bacteria were present but were overgrown by *Proteus* species. *Streptococcus fecalis* is another aerobic lactose fermenter. Greer¹⁰⁸ did not find it commonly present in Chicago water, probably due, however, to the methods which were used for its detection.

7. *Formation of gas due to symbiosis ("synergism").* Gas formation has been shown to be possible by Sears and Putnam¹²⁹ when two species of bacteria grow together in the presence of a carbohydrate when neither organism growing alone can produce it. Holman and Meekison¹³⁰ proposed the name "synergism" for this phenomenon. They stated that one of the species must be able to ferment glucose. Leitch¹²⁵ believed that this phenomenon might explain many of the positive presumptive tests which would not confirm. He isolated a number of pure cultures and found that gas resulted from certain combinations, whereas no gas was formed when the pure cultures were grown alone. He stated that one member of the combination had to produce acid from glucose. Holman and Meekison's experiments involved the use of *Streptococcus fecalis* and *Escherichia coli*. The former organism splits sucrose with the formation of acid and the latter had no action. When the two organisms were grown together gas was produced. Such results may also be secured in the fermentation tube.

Atkinson and Wood¹¹⁵ believed that synergism explained many false presumptive tests. Of 112 false positive tests, 84 were of this type. Similar observations were reported by Thompson¹¹⁶ and Graham.¹³² Graham called attention to the synergic reaction in production of gas from mannitol by *Eberthella typhosa* and *Salmonella morgani* when grown together, though neither bacillus gives this reaction when grown separately. *Eberthella typhosa* grown alone in the medium produced an intermediate substance which, when the *Eberthella typhosa* was killed, was decomposed with development of gas by the *Salmonella morgani* grown subsequently in the medium. Acid formation in the medium hindered growth of organisms and so hindered gas formation. The hydrogen-ion concentration should, therefore, be adjusted at intervals. A larger proportion of hydrogen was formed by the organisms acting alone on glucose or mannitol, and this corresponded with that produced by the glucose-fermenting organisms when acting alone on formates.

Synergism was also found to be one of the causes of spurious presumptive tests in analysis of Ohio River water by Evans.¹³³ Attempts to isolate an anaerobe were unsuccessful but an aerobic sporeformer which produced gas slowly and a non-gas-producing sporeformer were isolated which together gave violent gas formation and produced butyric acid.

8. *Dissolved Air in Presumptive Test Media.* When such media are stored in tubes at low temperatures, many of them may contain enough

129. Sears and Putnam. 1923. J. Infect. Dis. 32, 270-279.

133. Evans. 1937. Fourteenth Ann. Rept., Ohio Conf. Water Purification.

air to produce bubbles when incubated at 37°C. Archambault and McCrady^{113a} recommended storage at 25°C. for only a limited period.

9. *Loss of Escherichia coli during confirmation.* Another reason for failure to confirm gas formation in the presumptive test is loss of *Escherichia coli* during the confirmatory procedure.

Another possible explanation is toxic action of dyes on bacteria. Not all of them used in culture media have been studied as Ritter¹³⁴ has done with fuchsin.

B. CONFIRMED TEST

Standard Methods of Water Analysis permits use of Endo's or eosin-methylene blue plates or any of the liquid media: brilliant green lactose bile, crystal violet lactose broth, fuchsin lactose broth or formate ricimolate broth. All of these media were said to be equivalent in value.

1. ENDO OR EOSIN METHYLENE BLUE PLATES

1.1. Streak one or more plates from a tube which shows gas formation in lactose broth from the smallest amount of water tested. It is desirable to make transfers as soon as possible after gas formation occurs. In order to obtain typical results it is essential that the plates be streaked so as to insure the presence of some discreet colonies. Transfers should be made not later than at the end of the first 24-hour incubation period if gas has formed during this time. If at the end of 48 hours gas has formed in tubes containing less of the sample of water than at 24 hours, transfers should be made from these tubes. (For example, if the water has been tested in amounts of 10 ml., 1 ml., and .1 ml., and gas is formed in 10 ml. and 1 ml., not in .1 ml. the test need be confirmed only in the 1-ml. amount. But if the larger amounts are not transplanted for confirmation, they shall be recorded as confirmed, even though the smaller portion may fail subsequently to confirm.)

1.2. Incubate the plates at 37°C. (98.6°F.) for 18 to 24 hours.

1.3. Results, typical and atypical. If typical colonies have developed upon the plate within this period, the confirmed test may be considered positive. If, however, no typical colonies have developed within 24 hours, the test cannot yet be considered definitely negative, since it not infrequently happens that members of the coli-aerogenes group fail to form typical colonies on Endo or eosin methylene blue plates, or that the colonies develop slowly. In such case, it is always necessary to complete the test as directed under D.

2. LIQUID CONFIRMATORY MEDIA

2.1. Transfer from a lactose broth tube showing gas to the fermentation tube containing the selected confirmatory medium. It is recommended that all lactose broth tubes showing gas be confirmed to comply with this test, but it is allowable to follow the recommendations in C, 1. Transfers should be made as soon as gas appears within the 48-hour incubation period. In routine testing it is convenient to make observations and transfers if required at the end of 24 and 48 hours. In making transfers from the lactose broth fermentation tubes showing gas, the tube should first be gently shaken or mixed by rotating and the transfer should be made by means of a wire loop, the loop to be not less than three mm. in diameter; or it is permissible to use a sterile capillary tube or sterile pipette when it is considered desirable to transfer larger amounts. (From *Standard Methods of Water Analysis*, 8th Edition, pp. 212-213.)

2.2. Incubate the inoculated tubes containing the confirmatory medium for 48 hours at 37°C.

2.3. The formation and presence of gas in any amount in the inverted vials in the fermentation tubes at any time within 48 hours constitutes a confirmed test.

113a. Archambault and McCrady. 1942. Amer. J. Pub. Health 32, 1164-1168.

134. Ritter. 1940. Amer. J. Pub. Health 30, 59-65; 28 (1938) 616-620.

To find the best medium for the confirmed test, many comparative investigations have been made. Hoak¹³⁵ presented a fine summary of this situation as well as results of a comparative study made by himself. Except for the direct pour-plate methods, none of the differential tests mentioned were believed to be reliable enough to give dependable results without the supporting evidence of other related tests. Indol production, methyl-red and Voges-Proskauer reactions, and the citrate test when used together afford the most reliable differential group of tests now in use. Direct pour-plate media, however, offer the most promise for the future of coli-aerogenes differentiation. It is interesting that several investigators found lactose broth to be just about as useful as some of the special media. Ruchhoft,¹³⁶ Ruchhoft and Norton,¹³⁷ Atkinson and Wood,¹³⁸ Horwood and Heifetz,¹³⁹ all spoke well of this medium. McCrady¹⁴⁰ and Howard, Lochhead, and McCrady¹⁴¹ found brilliant green to be reliable for confirming lactose broth.

C. THE COMPLETED TEST

In the methods given below, attempt is made to determine whether gas secured in the presumptive test was formed by *Escherichia coli*.

1. 1. Streak one or more Endo or eosin methylene blue plates from the lactose broth tubes which show gas from the smallest amount of water tested or from the secondary selective medium tubes which show gas. If these plates are streaked from the original lactose broth tube they should be made at the same time that the secondary selective medium tubes are planted. If plates are used for the confirmed test, completion may be continued after incubation.

1. 2. Incubate the plates at 37°C. (98.6°F.) for 18 to 24 hours.

1. 3. Identification. From the plates fish one or more typical colonies, or if no typical colonies are present, fish two or more colonies considered most likely to be organisms of the coli-aerogenes group, transferring each to an agar slant and a lactose broth fermentation tube. The lactose broth fermentation tubes thus inoculated shall be incubated until gas formation is noted—the incubation not to exceed 48 hours. The agar slants shall be incubated at 37°C. for 24 hours, when a microscopic examination for the presence of spores and a Gram stain of at least one culture shall be made, selecting when possible the one which corresponds to one of the lactose broth fermentation tubes which has shown gas formation. If none of the lactose broth fermentation tubes contain gas at the end of 24 hours, all the agar slants shall be examined, and corresponding tubes examined on the following day.

1. 4. Results. The formation of gas in lactose broth and the demonstration of Gram-negative, nonsporeforming bacilli in the agar culture shall be considered a satisfactory completed test, demonstrating the presence of a member of the coli-aerogenes group.

Absence of gas formation in lactose broth or failure to demonstrate Gram-negative, nonsporeforming bacilli in a gas-forming culture constitutes a negative test.

When sporeforming, lactose-fermenting organisms are found, the culture should be further studied to ascertain the possible presence of bacteria of the coli-aerogenes group with the spore-bearing organisms. This may be done by transferring the culture to formate ricinoleate broth and incubating at 37°C. for 48 hours. If no gas is produced, only sporeforming lactose fermenters are present. If gas is produced in the formate

ricinoleate broth, members of the coli-aerogenes group may be present. If gas is produced, the presence of coli-aerogenes group organisms should be verified by inoculation of a tube of standard lactose broth and an agar slant. If, after 48 hours, gas is produced in the former and no spores are present in the latter, the test may be deemed "completed." If spores are present, for practical purposes the organisms of the coli-aerogenes group may be considered absent. (From *Standard Methods of Water Analysis*, 8th Edition, pp. 213-214.)

At one time this separation of coliform bacteria into fecal and non-fecal types was considered to be sharp and reliable. More experience, however, indicated that too much confidence had been placed in it. *Aerobacter aerogenes* was frequently found in excreta and *Escherichia coli* was occasionally isolated from materials which had a satisfactory sanitary history. Horwood and Webster¹⁴² attributed considerable sanitary importance to *Aerobacter aerogenes*. They also believed that *Escherichia coli* might be a derivative of *Aerobacter aerogenes* in the human body. Raghavachari and Iyer¹⁴³ also believed that opinions about sanitary significance of *Aerobacter aerogenes* would have to be changed. This opinion seems to be well supported by Cruickshank, in an unpublished communication to the Pathological Society of Great Britain and Ireland, who isolated from 98 to 135 specimens of human feces. In 24 of the 37 specimens that gave negative results, he ascribed his failure to isolate that organism to an overgrowth of the cultures with *Pseudomonas pyocyanea*. Gray,¹⁴⁴ examining 40 specimens of feces from 10 human subjects, and employing in addition to other methods the lithium containing medium that he has previously described, which inhibits the growth of *Pseudomonas pyocyanea*, isolated *Aerobacter aerogenes* from 37 of the samples. The frequent reports, especially in tropical countries, of the presence of methyl-red positive, citrate positive strains in samples of water taken from apparently unpolluted sources have led to the view that these intermediate forms should be grouped, in respect to their sanitary significance, with *Aerobacter aerogenes* rather than with *Escherichia coli*. Gray concurred in the opinion that a clean dichotomy of habitat does not in truth exist. This seems to be borne out by a recent investigation by Krishnan and Chawla¹⁴⁵ in which they studied the incidence of coliform types in stools of persons suffering from specific intestinal infections. They concluded that *Aerobacter aerogenes* should be considered an indicator of pollution even though it may be present in other situations than in the intestines of man and animals. Until a satisfactory method is found with which to distinguish between strains from soil and from feces, no definite opinion as to the sanitary significance of *Aerobacter aerogenes* in water can be given.

Weiss and Hunter's¹⁴⁶ Method for Bacteriological Examination of Water. A simplified method for determining the potability of water was developed and compared with the standard method. The new or "bottle" method consisted of adding five ml. of a concentrated broth (24 gm. of nutrient broth (Difco) to 100 ml. of water) to the sample bottle containing approximately 150 ml. of water, thus making 155 ml. of

142. Horwood and Webster. 1937. J. Bact. 33, 21.

143. Raghavachari and Iyer. 1940. Indian J. Med. Res. 28, 55-60.

144. Gray. 1932. J. Hyg. 32, 132-142.

145. Krishnan and Chawla. 1941. Indian Med. Gaz. 76, 628-631.

146. Weiss and Hunter. 1938. J. Bact. 36, 312.

nutrient broth. After adding the concentrated broth to the water in the bottle, the mixture was incubated at 37°C. overnight. The next day a loopful of broth from the bottle was streaked on a plate of eosin-methylene blue agar. Confirmation was carried out in the usual manner.

The "bottle" method was compared with the standard method using 638 water samples. It was found that 29.4 per cent of the samples gave positive results by both methods, that 60.2 per cent were negative by both methods, and that there was disagreement in 10.2 per cent. Of the 65 water samples showing disagreement, the standard method was positive and the "bottle" method was negative in 1.9 per cent of the samples, and the standard method was negative and the "bottle" method was positive in 8.3 per cent of the samples. Thus, the difference in favor of the "bottle" method was 6.4 per cent.

Sterile bottles containing the required amount of concentrated broth were sent into the field for trial with a number of samples of water. The results were excellent. The "bottle" method proved to be much more rapid and yielded fewer false reactions. Thus, while being more efficient, it was simpler and more economical.

Ministry of Health of Great Britain Procedures for Examination of Water for Coliform Bacteria. To provide uniformity in procedures, the Ministry of Health of Great Britain¹⁴⁷ prepared the following technic for determining coliform bacteria in water.

The procedures include the plate count, the presumptive coliform count, and the differential coliform test. They are not considered as a rigid set of rules from which any deviation is deprecated but rather a technic which is accompanied by the smallest error and which may be followed by bacteriologists in various laboratories. The British procedure for the plate count is given in full on page 164.

Technic of the Presumptive Coliform Count:

"(a) Inoculation of the MacConkey Broths—With good waters one 50 ml. quantity and five 10 ml. quantities of water should be inoculated into MacConkey broth; with medium waters one 50 ml., five 10 ml., and five 1 ml. quantities should be used; with poor waters five 1 ml. quantities of a 1 in 10 dilution should be included in addition, the single 50 ml. quantity being omitted if desired. The mixing of the water in the sample bottle and the preparation of the dilutions are carried out in the same way as in the plate count. Except with very bad waters, only a single dilution (1 in 10) is required.

"In the actual process of inoculation a sterile 1 ml. delivery pipette should be introduced into the bottle or test tube containing the 1 in 10 dilution of water with its tip reaching not more than 1 in. below the surface of the diluent. The fluid should be sucked up ten times to the 1 ml. mark in order to wet the interior of the pipette thoroughly and 1 ml. of fluid should then be measured out, the pipette being held in the vertical position. The pipette should be withdrawn and the tip touched against the neck of the bottle, or the side of the test tube, to remove excess fluid adhering to its exterior. It is then introduced into a tube containing 5 ml. of *single strength* MacConkey broth with the tip touching the side of the tube about 1 in. above the level of the broth. The contents should be blown out, 3 seconds allowed to elapse, and the last drop blown out. With the same pipette a fresh 1 ml. quantity is taken up from the 1 in 10 dilution and inoculated into a second tube of MacConkey broth. The process is repeated till all five tubes of broth have been inoculated from the 1 in 10 dilution. The same pipette is then transferred to the sample bottle containing the original water. The water is sucked up ten times to the 1 ml. mark, and five more tubes of single strength

147. Reprinted by permission of the Controller of His Britannic Majesty's Stationery Office from Reports on Public Health and Medical Subjects No. 71 (Revised Edition, 1939), entitled "The Bacteriological Examination of Water Supplies," official copies of which may be purchased from the British Information Service, 30 Rockefeller Plaza, New York, N. Y.

MacConkey broth are inoculated in the same way as before. The pipette is then discarded.

"A sterile 10 ml. pipette should then be taken and inserted into the sample bottle containing the original water with its tip reaching not more than 1 in. below the surface. The water should be sucked up ten times approximately to the 10 ml. mark, and 10 ml. of water should be measured out, the pipette being held in the vertical position. The pipette should be withdrawn and the tip touched against the neck of the bottle about $\frac{1}{2}$ in. below the rim so as to remove any excess water adhering to the *double strength* MacConkey broth, the tip being held about 3 ins. above the surface. The pipette should be allowed to discharge by gravity in the vertical position, and before removal its tip should be touched against the side of the test tube about 1 in. above the level of the medium. The same pipette is used to inoculate a total of five *double strength* MacConkey broths. It is then discarded.

"Finally, using a bulb pipette, one 50 ml. quantity of the original water should be inoculated into a bottle or large tube containing 50 ml. of *double strength* MacConkey broth. The transfer should be made under the same conditions as those used for the 10 ml. quantities, but is advisable in the interests of sterility not to suck the water up in the pipette more than once or twice before carrying it over to the medium for inoculation. The pipette is then discarded.

"*Incubation and Examination of the MacConkey broths.*—The inoculated MacConkey broths should be incubated at 37°C. and examined after 18 to 24 hours. All tubes showing both acid and gas formation should be regarded as "presumptive positives."

"It may be noted that the amount of gas formed depends partly on the type of organism and partly on the nature of the peptone used. Typical coliform organisms, particularly *Bact. Coli* I, usually produce sufficient gas in 24 hours to displace at least a quarter of the medium in the Durham tube. Organisms of the I. A. C.* group, on the other hand, though often producing as much or more gas than *Bact. coli* I, may produce little or none during the first 24 hours, and perhaps only a small amount after 48 hours. Some of them grow much better at 30°C. than at 37°C. If, in a series of routine examinations, the amount of gas formed seems to be unusually small, it is well to try another brand of peptone.

"For practical purposes readings should be taken at the end of 18-24 hours, and all tubes showing acid and an amount of gas sufficient or more than sufficient to fill the concavity at the top of the Durham tube reported as positive. If it should be judged desirable to undertake confirmatory and differential tests, the presumptive positive tubes should be treated in the way described later. The remaining tubes should be re-incubated and examined after another 24 hours. Any further tubes in which acid and gas formation become apparent should similarly be regarded as "presumptive positives" and submitted, if necessary, to further examination. In routine control work, however, if a number of tubes show acid and gas in the first 24 hours, there is usually no need to re-incubate the negative tubes."

Reporting Results. Specific instructions are given for reporting results. Owing to the fact that so much space would be required, they will not be given here.

TECHNIC OF DIFFERENTIAL COLIFORM TEST

A. Plating Method. One or two of the fermented MacConkey broth tubes—usually those seeded with the smallest quantity of water—are plated out on to a suitable solid medium.

"In this country, MacConkey's neutral-red bile-salt lactose agar plates are ordinarily used. Other valuable media are, however, much employed abroad, as, for example, Endo agar and Eosin-methylene-blue agar (Levine). It is claimed for some of these media that they enable the observer to differentiate between *Bact. coli* and *Bact. aerogenes* by direct inspection of the colonies. With Eosin-methylene-blue agar, differences between the colonies of *Bact. coli* and *Bact. aerogenes* can, in fact, often be made out within 24 hours, though in 48 hours differentiation is much easier. The formulae for the

* Intermediate-aerogenes-cloacae group.

preparation of these media will be found in Appendix C* and it is hoped that workers in this country who have the opportunity of doing so will employ them and report their results.

"Petri dishes of standard size into which about 15 ml. of melted MacConkey agar have been poured *without bubbles* and allowed to set, are first well dried by several hours' incubation at 37°C. (or, preferably, by one hour in an incubator at 55°C.) in the inverted position and with the inner dish, which contains the medium, supported on the edge of the cover; such dried agar plates may be kept in stock, wrapped in paper, for several weeks in the refrigerator. A loopful (1 to 2 mm. diameter) of the primary culture, or preferably of a dilution of it prepared by mixing one loopful with one ml. of sterile broth, is then placed half way between the center and the edge of the plate and spread over the surface by a sterile right-angled glass rod. In spreading, the drop should first be well-distributed along the contact portion of the rod (about 1½ in. long) by a to-and-fro motion and the rod then drawn round the rest of the plate; it should be kept gently but firmly in contact with the medium and parallel with the radii, until it has almost completed a circuit. Interruptions in the circuit by lifting the rod and reapplying a short distance further on help to increase the number of isolated colonies which is the object of plating; the rod should not cover the same surface of agar more than once. Other devices for obtaining isolated colonies, e.g., previous dilution of the primary culture, parallel and cross striations with a loop or straight wire, may be used according to personal preference.

"The plate is then incubated, bottom up, at 37°C. for 24 hours.

"*Appearance of colonies; subculturing for differential tests.*—On MacConkey agar coliform colonies are usually circular in shape, convex or low convex in elevation, with a smooth surface and an entire edge. They are coloured red, but the depth of tint varies considerably. The normal colony of *Bact. coli* is deeply coloured and non-mucoid, whereas that of *Bact. aerogenes* is often a paler colour and mucoid in consistency. For further examination two or three coliform colonies, as far as possible of different appearance are selected and subcultured. Should no typical colonies appear on the plate within 48 hours, it is well to select at least one of the predominant variety for further investigation bearing in mind the possibility that such atypical colonies may owe their absence of redness to a mere temporary slowing of their action on lactose. Should there be any doubt in the observer's mind whether the colonies selected are those of coliform or coliform-like bacilli, a film preparation should be made and stained by Gram. Only colonies consisting of Gram-negative, non-sporing rods should be subcultured.

"In the process of subculture a speck of the bacterial mass forming the colony should be picked off with a straight wire, suspended thoroughly in a tube of peptone water, and incubated at 37°C. After 4-6 hours' incubation the culture should be used for the inoculation of two tubes of glucose phosphate medium for the methyl-red and Voges-Proskauer tests, one tube of citrate medium for the citrate-utilization test, one tube of gelatin for the liquefaction test, one tube of MacConkey's broth to test for gas production at 44°C., and one tube of lactose peptone water for confirmation of lactose fermentation. The original peptone water culture can be reincubated and used to test for indole formation.

"*Technique for Differential Tests*—In the performance of these various tests, the following procedures are recommended.

"(1) *Indole Test*—The peptone water culture already referred to is removed from the incubator after three days and 1 ml. of ether added to it with vigorous shaking. It is then allowed to stand for a minute or two to allow separation of the ether layer containing any dissolved indole, and a few drops (0.5 ml.) of Erlich's reagent are allowed to run down inside the test tube. If the test is positive, the pink colour of rosindole appears within a few minutes.

"An alternative method, that of Holman and Gonzales¹⁴⁸ (1923), which is said to be slightly more delicate, makes use of the volatility of indole at 37°C. It consists in

* The reader is referred to Chapter 26 for a discussion of Culture Media and the changes which occur in differential media.

148. Holman and Gonzales. 1923. J. Bact. 8, 577.

placing a strip of filter paper, soaked in a saturated water solution of oxalic acid and subsequently dried, between the cottonwool plug and the tube at the time of inoculation. The paper should be carefully folded so as to present the maximum surface to the volatilizing indole during the growth of the culture. If indole is formed, the paper is turned pink.

“(2) *Methyl-Red Test*—Glucose phosphate broth is inoculated with a loopful of the stock peptone water culture 4-6 hours old, and incubated for three days at 37°C. Five drops of 0.04% methyl red solution are then added to the culture. A magenta red colour is considered a positive result: a yellow colour is negative; pink or pale red are best considered as doubtful results.

“(3) *Voges-Proskauer Test*—Glucose phosphate broth, similarly inoculated and incubated for two days at 37°C. has added to it 5 ml. of a 10% solution of sodium hydroxide. The result is read after the tube has stood 24 hours at room temperature, or after heating the mixture to near boiling point for about half an hour. If positive, a pinkish-green fluorescent colour develops; if negative, no colour.

“A modified method has been put forward by O'Meara:¹⁸⁹ A knife point of creatine is introduced into the culture as above and 5 ml. of 40% potassium f.c. hydroxide are added. The tube is shaken for two to five minutes. If positive, a pink colour develops; if negative, no colour.

“(4) *Growth in Citrate*—Tubes of citrate medium should be inoculated from the stock peptone water culture of 4 to 6 hours' age by means of a straight wire, not a loop, so as to carry over as little as possible of the inoculating medium. The tube is then incubated for 24 hours at 37°C., or if no growth has occurred, for 48 hours. Opacity is considered evidence of growth. If difficulty is experienced in determining the presence of opacity, brom-thymol-blue may be added in 0.008% concentration as an indicator. Growth is accompanied by a change in colour from a pale green to a bluish-green or blue. Occasionally no growth may be evident for 3 or 4 days.

“(5) *Gelatin liquefaction*—Inoculation of the solid medium should be performed with a straight needle charged with the stock peptone water culture (stab culture) or with a loop on the surface (slope culture), and the tube incubated at 20°-22°C. for 7 days. This time may be prolonged, if desired, to 21 days.

“(6) *44°C. MacConkey test*—The success of this test depends on the most rigid conformity to the technique about to be described. If an accurately regulated 44°C. water bath is not available, the test should be omitted. A tube of single-strength MacConkey broth should be heated in a water bath to 44°C., and then inoculated lightly from the peptone water culture. It should be immediately returned to the 44°C. water bath, and examined after 18-24 hours. The presence of gas in the enclosed Durham tube is regarded as a positive reaction; absence of gas formation, even though growth or acid production is present, is regarded as a negative reaction. If no gas is present after 18-24 hours, the tube should be reincubated for a further 24 hours. Very occasionally a strain of fecal coli may not form gas for 72 hours, but under ordinary routine conditions the tubes may be discarded as soon as gas is evident, or after 48 hours' incubation. Gas production under these conditions is practically characteristic of *Bact. coli*, type I, faecal. Except for quite occasional irregular strains, the only other organism in this country likely to be met with giving a positive reaction in this test is Irregular II.

“It is very important that the water bath used should be maintained at a temperature of 44°C. with only the minimum variation. The bath should be properly lagged; it should be placed in a part of the laboratory that is free from draughts and from direct sunshine; and the temperature should be regulated with a mercury-toluol or other reliable thermostat. The indicator thermometer should be checked against an N.P.L. standard, and should have its bulb placed at the level of the medium in the MacConkey tubes. It is advisable, in addition, to use a continuous recording thermometer in order to make certain that the temperature does not depart from the 44°C. level by more than .5°C. Two control tubes of MacConkey broth should be included, one inoculated with

a known strain of *Bact. coli* the other with a known strain of intermediate or aerogenes type. If, for any special purpose, an even greater degree of temperature control should be required, a constant temperature bath of the type described by Temple & McClemon¹⁴⁹ may be used.

“(7) *Fermentation of lactose*—A tube of lactose peptone water is inoculated with a loopful of the peptone water culture, and incubated at 37°C. All the members of the coliform group produce acid and gas from lactose, the great majority within 24 hours. Some strains, however, particularly of the I. A. C.* types, ferment lactose very slowly, and may form only a minimal amount of gas. Some of these strains grow much better and produce more active fermentation at (22°-30°C.) than at 37°C.

“B. Selective liquid media method. The rationale and general description of this method have already been given on pp. 32-34. It was pointed out that the original method was not altogether suitable for water analysis, but that modifications of the method might prove useful. The three modifications suggested are as follows:

“(1) The presumptive positive MacConkey tubes at 37°C. are subcultured into MacConkey at 44°C. and incubated for 24-48 hours. The presumptive fecal coli count is calculated by means of the ordinary probability tables from the proportion of tubes at 44°C. showing gas formation. If no gas is produced in any of the 44°C. tubes or in only a very small proportion of them, the original fermented 37°C. MacConkey tubes that remain negative on subculture at 44°C. are inoculated into Koser's citrate at 37°C. Growth within 2-3 days is regarded as presumptive evidence of the presence of I. A. C. organisms. Since the citrate test is not strictly specific under these conditions for organisms of the I. A. C. group, but may be given by late lactose fermenters or glucose fermenters, it is wiser not to express the results in probable numbers, but to confine the report to saying that the coliform organisms present appeared to belong to the I. A. C. or to irregular types. The occurrence of a certain proportion of false positives due to atypical organisms is to some extent counterbalanced by the rapidity and ease of the test, and by the fact that, even though typical I. A. C. organisms may not be present, late lactose fermenters and glucose fermenters are regarded by some workers as indicative of a minor degree of pollution and should not therefore be completely ignored.

“(2) As in (1) the fermented 37°C. MacConkey tubes are subcultured into MacConkey at 44°C. for the presumptive fecal coli count. If the 44°C. tubes are negative, the original fermented 37°C. tubes are plated on to MacConkey's agar, and colonies are picked off the following day and identified by the tests already described under the Plating Method. By this method, which takes at least four days, the coliform organisms present can be identified, and mentioned in the report.

“(3) If only the fecal coli count is required, or is required very rapidly, the original water can be inoculated into MacConkey broth and incubated at 44°C. The presumptive fecal coli count can be estimated after 1-2 days from the probability tables. It is possible that this method may slightly underestimate the fecal coli count, but for certain purposes this risk may be worth taking.

REPORTING THE RESULTS OF THE DIFFERENTIAL COLIFORM TEST

“(a) *When Method A is used*—It has been pointed out at some length that the proportions of coliform colonies of different types on the MacConkey plates correspond as a rule to the proportions in the fermented MacConkey tubes from which the plates were made rather than to the proportions present in the original water. For this reason it is advisable not to make any numerical estimate of the proportions of the different types of coliform bacilli present in the water itself, but to confine the report to stating that the presence of *Bact. coli*, *Bact. aerogenes*, or other coliform types was demonstrated by the usual differential tests in tubes seeded with a given amount of water. For example, supposing in Table II acid and gas were produced in one tube of 50 ml.

149. Temple and McClemon. 1937. Med. Officer 58, 241

* Intermediate-aerogenes-cloacae (I.A.C.) group.

and two tubes of 10 ml., and supposing the 50 ml. tube and one of the 10 ml. tubes were plated out, with the result that colonies of fecal coli were found on both plates, and colonies of *Bact. aerogenes* only on the plate made from the 50 ml. quantity, then the report might read as follows:

"Probable number of coliform bacilli present—6 per 100 ml. of water.

"Fecal coli were demonstrated in 50 ml. and 10 ml. of water.

"*Bact. aerogenes* was demonstrated in 50 ml. of water.

"(b) *When Method B₁ is used*—If gas is produced in the MacConkey broths at 44°C. that were seeded from the fermented 37°C. MacConkey tubes, and fecal coli are thus shown to be present, the report should simply state the probable numbers of coliform bacilli and of fecal coli present. For example, supposing . . . gas were produced in one 50 ml. and two 10 ml. quantities, and subcultures of each tube into MacConkey at 44°C. produced gas, then the report might read as follows:

"Probable number of coliform bacilli present—6 per 100 ml. of water.

"Probable number of fecal coli present—6 per 100 ml. of water.

"If no fecal coli were present and subculture of the fermented 37°C. MacConkey tubes into citrate was undertaken as in method B (1), and growth occurred in citrate, then attention should be drawn in the report to the presence of coliform organisms of non-fecal type. Since, however, the citrate test is not strictly specific for organisms of the I. A. C. group, but may be given by late lactose fermenters or by glucose fermenters, it is wiser not to express the results in terms of probable numbers, but to confine the report to saying that the coliform bacilli present appeared to belong to I. A. C. or irregular types. As an example, the report might read thus:

"Probable number of coliform bacilli present—6 per 100 ml. of water.

"Fecal coli absent from 100 ml. of water.

"Coliform organisms appear to belong to the intermediate-aerogenes-cloacae or to irregular types.

"If fecal coli were present, but in numbers constituting only a small proportion of the total coliform organisms, and subculture into citrate of the fermented 37°C. MacConkey tubes that remained negative on subculture at 44°C. was undertaken in order to confirm the presence of other types of coliform bacilli, and growth in citrate occurred, then this should be noted in the report. Thus supposing in the previous example, only one of the 10 ml. tubes at 37°C. when subcultured into MacConkey broth at 44°C. produced gas, the other 10 ml. tube and the 50 ml. tube remaining negative, and subculture of these last two tubes into citrate yielded growth, then the report might read as follows:

"Probable number of coliform bacilli present—6 per 100 ml. of water.

"Probable number of fecal coli present—1 per 100 ml. of water.

"Majority of coliform organisms present appear to belong to the intermediate-aerogenes-cloacae or to irregular types.

"*When Method B₂ is used*—If no fecal coli are present, or present in numbers constituting only a very small proportion of the total coliform organisms, and the fermented 37°C. MacConkey tubes are plated out as in method B (2) and the resulting colonies identified, the report might read as follows:

"Probable number of coliform bacilli present—6 per 100 ml. of water.

"Fecal coli absent from 100 ml. of water.

"*Bact. aerogenes*, or other identified type, was demonstrated in 50 and 10 ml. of water.

"*When Method B₃ is used*—If only the number of fecal coli present in the water is required, and method B (3) is used, the report can simply state whether fecal coli were present in 100 ml., and if so what their probable numbers were. If, for example, in Table II gas was produced in the tube of MacConkey broth at 44°C. seeded with 50 ml. of water, but not in any of the five tubes seeded with 10 ml., then the report would read as follows:

"Probable number of fecal coli present—2 per 100 ml. of water."

American Public Health Association Method for Differentiation of Members of the Coliform Group. The eighth edition (1936) of *Standard Methods of Water Analysis* prescribes four tests for satisfactory differentiation of the coliform group into the *Escherichia coli*, *Aerobacter aerogenes*, and intermediate sections: *indol test*, *methyl-red test*, *Voges-Proskauer reaction*, and *sodium citrate fermentation test*. Additional tests may be added if desired. This work was not considered to be desirable in routine water work. If only two differential tests are desired, a combination of the indol and sodium citrate tests or methyl-red and sodium citrate tests may be employed. The following reaction classification for coli-aerogenes bacteria was published in *Standard Methods of Water Analysis*, eighth edition.

COLI-AEROGENES GROUP—REACTION CLASSIFICATION

Reaction combinations				Possible interpretation when isolated from water by the standard method		Common source
Indol	M. R.	V. R.	Citrate	Usually	Occasionally	Applies to pure strain members of C-a group only
+	+	—	—	<i>Esch. coli</i>	Predominant in feces about 50 per cent of total group in sewage
—	+	—	—	<i>Esch. coli</i>	Non-members of group	Minority form in feces
+	+	—	+	Mixture	Intermediate strain sometimes considered nontypical <i>Esch. coli</i>	Minority form in soil and sewage, rarely feces
—	+	—	+	Intermediate strain	Mixtures or slow secondary reacting <i>A. aerogenes</i>	Soil, minority forms in sewage and feces
+	+	+	+	Mixture	Atypical	Soil, sewage
+	—	—	+	Always mixture		
+	—	+	+	Mixture	<i>A. cloacae</i>	Soil, minority forms in sewage and feces
—	+	+	+	<i>A. aerogenes</i>	Mixture	Majority forms in soil and on vegetables
—	—	+	+	<i>A. aerogenes</i>		Up to 50 per cent of total group in sewage
—	—	—	+	Extraneous form	<i>A. aerogenes</i>	Minority forms in feces

These tests may be made as follows:

Methyl-Red Test. Inoculate the culture into 10 ml. of the standard peptone medium (dextrose potassium phosphate broth). Incubate at 37°C. (98.6°F.) for three or preferably four days. To five ml. of each culture add five drops of methyl red solution. Record distinct red color as methyl red +, distinct yellow color as methyl red —, and intermediate colors as ?.

Voges-Proskauer Test. To the remaining five ml. of medium add five ml. of a 10-per cent solution of potassium hydroxide. A positive test is

indicated by an eosin pink color. To hasten the appearance of the red color the tubes treated with sodium hydroxide should be incubated at 37°C.(98.6°F.) or 45°C.(113°F.) for six hours. The Werkman technic for hastening appearance of the pink color may be used if desired.

Sodium Citrate Test. The citrate medium should be inoculated only with a needle or loop. A pipette is prohibited on account of the ease of introducing nutrient material which would invalidate the results. Incubate the culture at 37°C.(98.6°F.) for 72 to 96 hours and record growth as + or —.

Indol Test. Determine indol formation in tryptone broth by adding, drop by drop, to avoid mixing with the medium, about one ml. of a two-per cent alcoholic solution of p-dimethyl amido-benzaldehyde, then a few drops of concentrated hydrochloric acid. The presence of indol is indicated by a violet color.

	Fecal type <i>Escherichia coli</i>	Non-fecal type <i>Aerobacter aerogenes</i>
Gas ratio	1 p. CO ₂ to 1 p. H.	2 p. CO ₂ to 1 p. H.
Hydrogen-ion conc'n.	Acid to methyl red	Alkaline to methyl red
Voges-Proskauer.....	V-P negative	V-P plus
Uric acid test as sole source of N.	No growth	Growth
Citric acid test source of carbon..	No growth	Luxuriant growth

Methyl-Red Test. As sanitary knowledge increased and it became apparent that *Escherichia coli* or bacteria of the coli group could be present on substances which had not received fecal pollution, studies were made to detect those *Escherichia coli* which came from fecal sources. Rogers¹⁵⁰ and his co-workers found that the gas ratio could be used for this purpose. *Escherichia coli* from bovine feces fermented dextrose with the formation of equal volumes of carbon dioxide and hydrogen while those from grains formed two or three times as much carbon dioxide. The next step was to find a simple procedure for determining this ratio or finding some procedure which correlated with it, since the determination of the gas ratio is too exacting for routine analyses. Clark and Lubs,¹⁵¹ working in the same laboratory, discovered a constant correlation between the gas ratio and the hydrogen-ion concentration. *Escherichia coli* strains from bovine feces were found to possess a higher hydrogen-ion concentration than those from grains or non-fecal origins. A study of indicators yielded the information that methyl red was yellow with the high-ratio group and red or acid with the low-ratio group.

Voges-Proskauer Reaction. Levine correlated the Voges-Proskauer¹⁵² with the methyl red test. He found that bacteria which gave the Voges-Proskauer reaction were rarely found in feces and that the Voges-Proskauer reaction, like the high-gas ratio and the alkalinity to methyl red, is characteristic of non-fecal strains and, therefore, of much sanitary significance. Harden,¹⁵³ in his various publications, reported his studies

on the chemistry of this reaction which are well reviewed by Levine.¹⁵⁴ The red color which results is due to a definite end product in the fermentation of glucose. Voges and Proskauer, in their original publication, describe the test as follows:

“On addition of caustic potash, we observed a new and interesting color reaction. If the tube be allowed to stand twenty-four hours and longer at room temperature, after the addition of the potash, a beautiful fluorescent color somewhat similar to that of a dilute alcoholic solution of eosin forms in the culture fluid particularly at the open end of the tube exposed to the air. We have investigated a few of the properties of this coloring substance which is not produced by the action of the alkali on the sugar and have found that it is fairly resistant to the action of the external air. After a time, however, it becomes paler, and finally gives place to a dirty greenish brown.”

Harden and Walpole¹⁵⁵ could not account for all of the carbon in the dextrose by the ordinary products (organic acids, alcohol, etc.); along with these substances was secured a glycol which was made up of 2:3 butylene glycol. This was oxidized to acetyl-methyl-carbinol.

When this was mixed with potassium hydroxide, in the presence of peptone, an eosin-like color was obtained after a period. Walpole¹⁵⁶ found that under aerobic conditions *Aerobacter aerogenes* gave a greater amount of acetyl-methyl-carbinol. The coloration was not secured when butylene glycol or acetyl-methyl-carbinol were mixed with potassium hydroxide. Harden¹⁵⁷ later explained this by finding that the acetyl-methyl-carbinol was oxidized to diacetyl $\text{CH}_3\text{CO—CO—CH}_3$. This, in some way, acted with peptone. This, in some way, acted with the peptone to give a pink color. Harden and Norris¹⁵⁸ later secured the same pink color between diacetyl and arginine, dicyanamide, creatin, and guanidine acetic. They state that the reaction depending upon the group $\text{NH}=\text{C}(\text{NH}_2)\text{—N}=\text{HR}$, R has not been determined. The origin of acetyl-methyl-carbinol was reported by Barritt¹⁵⁹ to be 2:3 butylene glycol and pyruvic acid, and in small amounts from lactic acid, but not from preformed acetaldehyde or methylglyoxal. This substance is also readily formed by *Escherichia coli* from 2:3 butylene glycol and to a slight but variable extent from high concentrations of glucose, pyruvic acid. Pyruvic acid may be an intermediate product in forming of acetyl-methyl-carbinol from glucose and 2:3 butylene glycol may perhaps be the immediate precursor. Differences in the production of the carbinol by members of the coli-aerogenes group appear to be quantitative rather than qualitative. Many organisms can oxidize 2:3 butyl glycol to acetyl-methyl-carbinol.

Several investigators have found that incubation temperature greatly affects the Voges-Proskauer reaction. To reduce this error, Bunker¹⁶⁰ sug-

gested the following technic which allows the test to be made in an hour and a half. Place one ml. of a glucose potassium phosphate broth culture incubated for 48 hours at 30°C. (86°F.) in a Syracuse watch glass, and add .5 ml. of a 45-per cent solution of sodium hydroxide. The definite color reaction (a deep pink) is secured in one and one-half hours. Linton¹⁶¹ also found that temperature of incubation was very important. Link isolated 37 strains of *Aerobacter aerogenes* which gave positive Voges-Proskauer reactions for 48 hours but which were negative on longer incubation. Levine, Weldin, and Johnson¹⁶² reported that the Voges-Proskauer reaction could be reported in five hours after addition of the potassium hydroxide to the test culture. It has also been suggested that the sugar content of culture media could be lowered. For instance, Burling and Levine¹⁶³ stated that one per cent of glucose or lactose in the medium and an incubation period of 48 hours was not favorable to isolation of *Escherichia coli*. They suggested that the amount of carbohydrate could be reduced to .5 per cent and the confirmatory tests applied more quickly. Wagner¹⁶⁴ reported that even .1 per cent of lactose gave better results than one per cent. Wagner and Monfort¹⁶⁵ advised the pasteurization of the carbohydrate media, rather than sterilization. They also stated that if sufficient peptone is added, the meat extract may be left out. Their findings with regard to pasteurizing instead of high pressure-temperature sterilization are in keeping with the work of Hasseltine¹⁶⁶ and Mudge,¹⁶⁷ but not in accord with Wolf's¹⁶⁸ statements that the dangers from combined sterilization have been overemphasized. In this paper they also advised reduction of the amount of lactose as did Wagner.

The methyl-red test and Voges-Proskauer reactions were introduced to differentiate fecal lactose-fermenting bacteria (*Escherichia coli*) from those which possessed no sanitary significance (*Aerobacter aerogenes*). Almost as soon as *Standard Methods* provided for this differentiation, results of investigators were published which suggested that such a differentiation could not exist. This was stated to be the situation by Monfort and Perry¹⁶⁹ who studied 391 cultures of coliform bacteria from natural waters and found that "intermediates" were common. They stated that averages and percentages do not always show the characteristics of these variants. They secured only imperfect correlation between the methyl-red test and the Koser uric acid reaction which seemed to be discriminative of *Aerobacter aerogenes*. A longer presentation of these data in 1921 by the same authors indicated again that the uric acid medium, discussed in another paragraph, was useful for separating the *Aerobacter aerogenes* type of organisms. Bardsley¹⁷⁰ examined 525 samples of water, 265 of which

contained lactose-fermenting bacteria; 1,441 strains were isolated and subjected to the various differential tests. Only 1.73 per cent were either double positive or double negative when tested with methyl-red and the Voges-Proskauer reactions. The small existence of these types was not regarded as indicating that they complicated the use of these tests under routine conditions. Bardsley stated that organisms should be regarded as significant which have typical morphology and staining reaction, produce acid and gas in lactose, fail to liquefy gelatin, clot milk, and give a positive methyl-red reaction and a negative Voges-Proskauer reaction.

Peragallo,¹⁷¹ after examination of many samples of soil from various Alpine mountain tops, found the predominating fermenter to be *Aerobacter aerogenes*. Examination of excreta from man, animals, and birds revealed *Escherichia coli*. Peragallo, therefore, placed great weight on presence of *Escherichia coli* in water as indicating pollution. Ferramola and Monteverde¹⁷² found birds to be the source of *Escherichia coli* in reservoirs. See gulls have also been found to pollute reservoirs.

There is, however, no question of the wide difference in frequency of these types in the different habitats examined. *Escherichia coli* is certainly the predominant coliform inhabitant of the intestine, *Aerobacter aerogenes* the predominant coliform inhabitant of the soil, and the intermediate type far more frequent in the soil than in the intestine. Bardsley¹⁷³ believed that, inasmuch as coliform bacteria were not widely distributed in nature except where fecal contamination had occurred, the differential tests might be discarded.

Irregular correlation of Voges-Proskauer reaction with the methyl-red test was also observed by Stovall and Nichols,¹⁷⁴ Berry,¹⁷⁵ Koser,¹⁷⁶ and Hicks.¹⁷⁷ These results soon led to the opinions that differentiation was necessary.

Stokes,¹⁷⁸ in studying this question, stated that a water could not be considered to be safe if but two or three colonies were studied from each specimen. He suggested that perhaps 20 or 25 colonies be examined from a water which has no evidences of pollution as determined by either laboratory examination or by sanitary inspection. Winslow and Cohen¹⁷⁹ reported results of a study of 255 strains of coliform organisms, 202 of which were methyl-red positive and 53 methyl-red negative. They could detect no marked differences between the organisms from different sources and stated that no necessity existed for differentiating between coliform organisms for determining sanitary quality of water. Many *Aerobacter aerogenes* organisms in water might indicate remote pollution.

Various investigators have at times desired to distinguish between coliform bacteria found in the feces of different animals and, in that way, to

find out what type of pollution was present in water or foods. Darling¹⁸⁰ isolated 113 strains of colon bacilli from feces, including 20 from man, 23 from horses, 23 from sheep, 26 from rabbits, and 21 from chicks, and found that none of them were of the *Aerobacter aerogenes* type, as determined by the methyl-red and Voges-Proskauer tests; this author stated that water may contain *Escherichia coli* from other sources than man, but that there was no means of differentiating them.

Levine's¹⁸¹ Method for Rapid Determination of the Colon Group. Levine suggested the following method for obtaining the standard presumptive and confirmed test simultaneously in 24 hours.

"From a consideration of the rates of growth of the coli-aerogenes group in broth it is contended that, if one organism capable of growing in the medium is introduced with 10 ml. of water into 30 ml. of broth, after an incubation period of 10 hours at 37°C. there should generally be over 2,000 bacteria in the tube, or 50 per milliliter. The number of these organisms is too small to show any visible evidence of growth, such as gas formation. If, however, .1 ml. were smeared over the surface of an eosin-methylene-blue agar plate, the organisms introduced onto the plate (theoretically at least 5) would grow very rapidly as they are in their logarithmic growth phase (i.e., the stage of most vigorous growth) so that colonies would develop very quickly, generally in 12 to 16 hours, on this solid medium. If these plates and the preliminary enrichment medium are both kept at 37°C. then those plates made from tubes which show gas the next morning (24 hours presumptive test) should have colonies of the coli-aerogenes group (partially confirmed test).

"A number of samples of the Missouri and Iowa river waters were tested in this way and it was found that in over 90 per cent of the trials, E. M. B. plates made after 10 hours' incubation from tubes which proved to be positive 24 hour presumptive tests were positive for the partially confirmed test."

The methyl-red test and Voges-Proskauer reaction are usually carried out at 37°C.(98.6°F.). Vaughn and Levine¹⁸² recommended 30°C.(86°F.) because at the higher temperature cultures of the aerogenes-cloacae group may fail to revert to alkaline reaction or to produce acetyl methyl carbinol. Strains of the coli type were unaffected. In practice it was recommended that in classifying coliform strains, cultures for the methyl-red test should be incubated for five days at 30°C.(86°F.) as originally prescribed by Clark and Lubs. The Voges-Proskauer test should be carried out on cultures incubated for one to two days at 30°C.(86°F.), and the Barritt method should be used for bringing out the color (.6 ml. of five per cent alpha-naphthol in absolute ethyl alcohol and .2 ml. of 40 per cent KOH added to one ml. of culture). The results of the O'Meara and the Barritt methods are, however, almost identical.

Werkman's¹⁸³ Improved Technic for the Voges-Proskauer Test. This method involves the use of ferric chloride as a catalyst to avoid some of the disadvantages of the original Voges-Proskauer reaction. The eosin-like color secured by the older technic is quite transitory. That secured by the suggested new technic gives a copper color which appears at the surface of the tube and extends to the bottom of the tube in a few minutes. This color was said to remain for several days and to be clearly visible for a week or longer. The test may be positive for organisms of the Aerogenes group after three days incubation at 30°C.(86°F.), but four-day cultures were recommended. Two drops

of a two-per cent solution of ferric chloride are added to five ml. of the culture. Five ml. of a 10-per cent solution of sodium hydroxide are then added and the tube shaken. The ferric chloride solution should be added before the addition of the sodium hydroxide, since a flocculation results if this is not done. The reaction may be accelerated by heating in boiling water for one minute.

Lindsey and Meckler¹⁸⁴ were able to confirm Werkman's conclusions. They found that identical results could be obtained with Werkman's technic when it was applied to 24-hour cultures. They said that ordinary glucose broth could be used in place of special media and results were more easily read than in the older test. They also attempted to distinguish between *Escherichia coli* and *Aerobacter aerogenes* by dye reduction. They observed that *Aerobacter aerogenes* reduced methylene blue in a lactose broth fermentation tube in a few minutes while *Escherichia coli* gave no visible reduction in several hours. This agreed with results of the Voges-Proskauer test in 44 out of 45 cases. The advantage of their technic is that much time is saved in running the Voges-Proskauer reaction.

Barritt's¹⁵⁹ Method for Voges-Proskauer Reaction. According to Barritt, addition of alpha-naphthol to the Voges-Proskauer reaction intensifies the reaction. The test is applied by adding one ml. of a culture, .6 ml. five-per cent alcoholic solution of alpha-naphthol, and .2 ml. 40-per cent potassium hydroxide. Color appears in two to three minutes and lasts four to 24 hours. The reaction, which is very delicate and specific shows that many species of bacteria which are usually considered unable to do so, produce acetyl-methyl carbinol.

According to Vaughn, Mitchell, and Levine¹⁸⁵ the technics recommended in *Standard Methods of Water Analysis* for the Voges-Proskauer reaction [24 to 48 hours at 37°C. (98.6°F.) with 10 per cent KOH as the test reagent], and for the methyl red test [three to four days at 37°C. (98.6°F.)] are not suitable for detection of the maximal number of positive strains in either case. The Barritt alpha-naphthol reagent and a temperature of 30°C. (86°F.) should be used. Iyer and Raghavachari¹⁸⁶ also advised Barritt's modification.

As previous workers have done, Tittsler¹⁸⁷ showed that the Voges-Proskauer reaction should be carried out on cultures not more than two days old; otherwise positive cultures become negative on further incubation. Whether this is due to fermentation of the acetyl-methyl-carbinol by the *Aerobacter aerogenes* group or to its reduction to 2:3-butylene glycol has not so far been clear. Tittsler, however, brought evidence to show that true fermentation does occur. Out of 90 strains of the aerogenes type, i.e., M. R. —, V. P. +, citrate +, 37 gave a positive V. P. reaction during the first three days and a negative one after five days. All of these 37 strains were found capable of growing and producing acid in a synthetic medium containing acetyl-methyl-carbinol as the sole source of carbon. The remaining strains were unable to ferment this substance, and gave a

187. Tittsler. 1938. J. Bact. 35, 157.

persistently positive V.P. reaction in the ordinary glucose broth medium. The 37 strains that fermented acetyl-methyl-carbinol comprised about half of the strains labelled *Aerobacter aerogenes* and *Aerobacter oxytoca*, but none of the strains labelled *Aerobacter cloacae*.

Bacteriologists in the laboratory of the Metropolitan Water Board of London,¹⁸⁸ found some of the technics recommended for the Voges-Proskauer reaction to yield faint and inconclusive reactions. This is the reason why so many modifications have been proposed. They compared O'Meara's¹⁸⁹ and Barritt's¹⁵⁹ technics and found both to agree on *Escherichia coli* and *Aerobacter aerogenes*; marked discrepancies were observed, however, with the "intermediate" group of coliform organisms. Their work was discussed as follows:

Four-day cultures grown at 37°C. in buffered glucose phosphate peptone water were tested for the Voges-Proskauer reaction in three ways:

1. *Old method*: Five ml. of 10 per cent caustic soda solution were added to five ml. of the culture, thoroughly shaken, and allowed to stand in the dark overnight at room temperature. Many of the reactions were faint and difficult to read, but the slightest trace of pink coloration was considered a positive.

2. *O'Meara's modification*: A knife-point of creatine and five ml. of 40-per cent caustic potash solution were added to five ml. of the culture and thoroughly shaken. Vigorous shaking was required to produce a coloration within 10 minutes with positive strains, but when left overnight deeper tints were obtained than with the old test, and no fading occurred. Ten-per cent caustic soda solution was found to act as well as the caustic potash solution.

3. *Barritt's modification*: One ml. of the culture was transferred to a clean, dry test tube, six inches by three-fourths inch in size, and .5 ml. of a six-per cent alcoholic solution of alpha-naphthol and .5 ml. of a 16-per cent solution of caustic potash added. A bright cherry-red coloration appeared within five to 15 minutes after shaking, but faded after a few hours.

Both the creatine and alpha-naphthol tests revealed more positives than the old method. Of the two modifications, alpha-naphthol produced 62 positives and creatine 57; also the color obtained with the former test was very distinct and few faint reactions were obtained compared with the other two tests. Twenty-five strains that were negative with the old method yielded positive results with alpha-naphthol, 16 of these were indole positive and nine were indole negative.

Tests with typical *Escherichia coli* and *Aerobacter aerogenes* showed the three methods to be in complete agreement, all coli strains were Voges-Proskauer negative and all aerogenes strains Voges-Proskauer positive.

Cultures giving the reaction "methyl red +, citrate +, Voges-Proskauer +, indole + or —," have been previously classed as irregular coliform types and probably mixtures of two or more known types. A number of "Methyl Red +, citrate +," cultures showing this irregular reaction with the old method of testing for acetyl methyl carbinol were carefully re-tested by repeated platings on the lines advocated by Ruchhoft (1932), and, although some were converted into pure types, no mixtures were encountered, and the majority continued to give anomalous results. With the alpha naphthol test more of these Voges-Proskauer positive organisms would be detected owing to the sensitiveness of the modification. In the future, such strains may be considered as a pure coliform type.

The alpha naphthol modification of the Voges-Proskauer test is welcome for its sharply defined coloration, obtainable within a few minutes. The modification shortens the time required to type a coliform organism by at least 18 hours. A comparative in-

188. Thirty-first Ann. Rept., Metropolitan Water Bd., London, for 1936, p. 21.

189. O'Meara 1931. J. Path. and Bact. 34, 401-406.

vestigation of the Barritt and O'Meara methods by Batty-Smith¹⁹⁰ revealed the former to give the most positive results. There was four per cent difference between the two methods. This difference was said to represent non-coliform bacteria.

Methylene-Blue Reduction Test for Distinguishing *Escherichia coli* from *Aerobacter aerogenes*. Lindsey and Meckler¹⁹⁴ suggested a methylene-blue reduction test for distinguishing *Escherichia coli* from *Aerobacter aerogenes*. They reported that when one drop of saturated aqueous solution of methylene blue was added to a 24-hour culture of *Aerobacter aerogenes* in a lactose broth fermentation tube, the dye was reduced within a few minutes. With *Escherichia coli* no visible reduction took place within several hours. Lindsey and Meckler stated that the lactose broth fermentation tube used in the "complete test" could be used for the methylene-blue reduction test.

Tests on 359 strains show that methylene blue will not distinguish between the genera, that oxidation-reduction potentials do not always parallel reduction of the dye, and that eosin-methylene-blue agar is a good index for behavior of these strains in lactose with respect to oxidation-reduction potentials (Epstein¹⁹¹).

Many modifications of the presumptive test medium have been proposed. Most of them involve addition of some substance which is supposed to inhibit other bacteria and either favor development of *Escherichia coli* or leave the field less encumbered for its development. These modifications have made it necessary to carry out many comparative studies with older media to determine whether the new proposal had merits. In some cases it was shown that newly proposed ingredients were inhibitory to *Escherichia coli* as well as to the other forms.

Lactose Peptone Bile. MacConkey in 1900, as discussed below, suggested a medium containing bile salts (sodium taurocholate) for differentiating *Escherichia coli* from *Eberthella typhosa*. Jackson¹⁹² probably was the first to use bile media in the United States. He departed, however, from MacConkey's medium by using ox-gall itself instead of bile salts. He proposed lactose broth with one per cent of bile as the standard medium. This medium was recognized in the second edition of *Standard Methods for the Examination of Water and Sewage* (1912) but not in the third edition published in 1917. It has never been an official medium in the United States. One reason for this may be that several investigators, Jordan¹⁹³ and Obst,¹⁹⁴ found that the bile inhibited *Escherichia coli* as well as other bacteria.

Much of the earlier work is contradictory. Cumming¹⁹⁵ in stream-pollution studies on the Potomac River, found lactose broth to be superior to lactose bile. On the other hand, Ritter¹⁹⁶ found lactose bile to be as satisfactory as lactose broth when comparisons were made on 1,899 sam-

ples of water. In an examination of 482 samples of water from farm wells, Lochhead and Hewer¹⁹⁷ found no advantage in lactose bile if the presence of coliform bacteria is regarded as the criterion of pollution; if, however, the fecal type of *Escherichia coli* is to be the criterion of pollution, lactose bile was better.

Seeking to determine the effect of bile on growth of *Aerobacter aerogenes* Levine¹⁹⁸ added varying amounts of sodium taurocholate and found that up to 1.5 per cent caused an acceleration of growth. Concentrations of about two per cent of evaporated bile stimulated the growth of *Escherichia coli*, but slightly inhibited *Aerobacter aerogenes*. Higher concentrations were inhibitory. According to Coles and Levine¹⁹⁹ evaporated bile may inhibit or stimulate the growth of *Escherichia coli* depending on the concentration of bile, reaction of the medium, and the strain of the organism used. With all samples of bile used, a concentration of two per cent accelerated growth, whereas five per cent inhibited in media having a pH of 6.0; in alkaline media (pH 7.3-7.8) the organism was stimulated.

According to Poe²⁰⁰ a bile content of five to seven per cent gives best results. Aerobic sporeforming, lactose-fermenting organisms were said to be inhibited by more than five per cent bile. Poe reported that boric acid in amounts of .1 per cent and above in bile-lactose media distinctly inhibited growth of both *Escherichia* and *Aerobacter* groups. Values of pH between 6.75 and 7.25 made little difference in growth of strains used. Aerobic sporeformers grew well in media containing boric acid up to .3 per cent. Anaerobes grew well in the boric acid-bile media. Boric acid-bile agar offered no advantages as a differential medium. Fuller²⁰¹ grew thirty carefully purified strains in a suitable medium to which one per cent or five per cent of bile or bile salts was added; cultures were transferred each week for five months. The results argue in favor of the stability of the cultural reactions of pure established cultures in so far as the influence of bile or bile salts alone is concerned.

MacConkey's Bile Salt Broth. This is an ancient and honorable medium in sanitary work, much better known to English bacteriologists than American. It was introduced by MacConkey²⁰² for differentiating intestinal bacteria. The coliform-inhibitor is sodium taurocholate to the amount of five grams per liter. *Escherichia coli* and *Aerobacter aerogenes* produce both acid and gas. Since 1901 MacConkey's broth has undergone modification. Dessicated bile has been largely substituted for sodium taurocholate and seems to give as satisfactory, if not better, results. It is probably the precursor of the various bile media which came after it and has been compared with the many other media proposed for the same purpose. MacConkey's broth is the standard medium in procedures of water analysis of the Ministry of Health of Great Britain.

Raghavachari and Iyer²⁰³ found MacConkey's medium to be superior to Dominick-Lauter's medium when applied to water collected in India. In fact they believed the MacConkey medium to be the most satisfactory one available for *Escherichia coli* tests. They compared a number of media, including lactose broth containing one per cent Andrade's indicator, MacConkey broth, crystal violet broth, the Dominick-Lauter medium, and a synthetic medium containing lactose, asparagin, and brom-cresol-purple, for use in the presumptive coliform test. The most sensitive medium was found to be lactose broth, and with this medium plating revealed coliform organisms in greater numbers than with any other medium. As has been found in Great Britain and Australia,²⁰⁴ MacConkey's broth yielded fewer presumptive positives than lactose broth, but in contradiction to experience in these countries attempts to confirm the presence of coliform organisms in presumptive positive MacConkey tubes frequently failed. In other words, MacConkey broth, like lactose broth, was often subject to false positive reactions. MacConkey's medium was found to be inferior to eosin methylene blue agar. Eosin methylene blue agar had the advantage of inhibiting the growth of non-lactose-fermenters to a greater extent than MacConkey agar. In practice they recommended the use of lactose broth for primary inoculation of water. Confirmation of tubes giving acid and gas within 24 hours is regarded as unnecessary. Tubes in which acid and gas formation is delayed for 48 hours should be plated on eosin methylene blue agar. The experience with MacConkey's broth in India does not parallel that in England. The reasons are not apparent. McCrady²⁰⁵ found that MacConkey's broth gave too many false positive tests which did not confirm. He preferred lactose broth with confirmation (gas only) in secondary brilliant green bile, two per cent.

The Metropolitan Water Board of London annual report for the year 1937 stated that MacConkey broth compared favorably in selective ability with brilliant green broth and Dominick-Lauter medium with various types of water which were analyzed. In fact, the results with these three media agreed so closely that each was considered about equally sensitive in demonstrating coliform bacteria. MacConkey broth proved superior in the case of stored water, which is an essential part of protective measures. With filtered waters there was a slight advantage in favor of brilliant green. On the other hand, Dominick-Lauter medium appeared to inhibit *Escherichia coli* slightly with consequent increase in frequency of atypical forms. The percentage of false presumptive tests was low in all media being less than eight per cent with the highest numbers in chloraminated river water undergoing storage and especially indicated that sporeforming, lactose-fermenting bacteria were almost completely suppressed by brilliant green bile and Dominick-Lauter media. MacConkey broth also exerted strong inhibitory powers which were attributed to its bile salt content. It was believed, therefore, that by using MacConkey primary enrichment medium water bacteriologists in England were not encountering the same diffi-

culties with respect to false presumptive tests that are encountered in America with plain lactose broth. Brilliant green was considered to be the best supporting medium for MacConkey. In March, 1938, the Metropolitan Water Board of London substituted brilliant green bile broth incubated at 37°C. (98.6°F.) for the indol test as confirmation of the 10-ml. MacConkey broth tube in the presumptive test. Results which were secured with this new combination of media suggest that the change was a fine one.

Formate-Ricinoleate Broth. This medium, devised by Stark and England,²⁰⁶ was found to inhibit organisms which give false-positive tests in the presumptive test in water analysis. This was attributed to the sodium ricinoleate. The sodium formate stimulated both growth and amount of gas formed by bacteria of the *Escherichia-Aerobacter* growth because they are able to produce gas from formic acid. Noble and White²⁰⁷ observed that formate ricinoleate broth, among many which were tested, was the only one which met requirements when compared with the standard medium.

Boric Acid Lactose Broth. Boric acid was added to lactose broth in the presumptive test by Vaughn and Levine²⁰⁸ to inhibit *Aerobacter aerogenes* and allow *Escherichia coli* to develop. They did observe a little evidence of inhibition of gas formation with some strains which grew. Poe and his colleagues²⁰⁰ observed inhibition of both *Aerobacter* and *Escherichia* species. Both aerobic and anaerobic sporeformers grew well in boric acid media containing .1 per cent of boric acid.

Dominick-Lauter Selective Medium. This medium was devised to shorten the time required for the presumptive test in water analysis. Dominick and Lauter²⁰⁹ claimed for it a saving of many hours. The medium is a lactose broth base to which a dye mixture made of erythrosin, methylene-blue and brom-cresol-purple is added. It was believed that lactose fermenters other than coliform bacteria, are inhibited leaving the field for the latter. Results of several comparative studies of various presumptive test media, including the Dominick-Lauter medium, have not always agreed. Leahy, Freeman, and Katsampes²¹⁰ found it superior to lactose broth, while Howard²¹¹ preferred brilliant green bile medium. Nolte and Kramer²¹² found it superior to other media as did Stewart.²¹³ The last mentioned, however, desired more information before giving up the regular medium. MacConkey's medium was superior to this one in the hands of Raghavachari and Iyer²⁰³

Inhibition of coliform bacteria must always be considered when other agents are added to the presumptive test medium. Dominick-Lauter's medium was reported by Evans and Bahlman²¹⁴ and Butterfield²¹⁵ to inhibit

coliform bacteria as well as the other water bacteria. In the hands of Butterfield it was more inhibitive than brilliant green bile.

DIRECT ENUMERATION OF COLIFORM BACTERIA IN WATER

Much time could be saved in sanitary work and more accurate results secured if coliform bacteria could be counted directly instead of using some of the indirect methods. It would obviate the necessity of using *Escherichia coli* index or "most probable numbers." Possibility of such procedure needs more study than has been given to it. Among others, the following have been used or proposed.

Eosin Methylene Blue Agar Medium. This plating medium was developed by Levine²¹⁶ for differentiating *Escherichia coli* from *Aerobacter aerogenes*. The differential characteristics are given in the chapter on "Media." This medium is accepted as a satisfactory medium in the "completed test" in water analysis where it is streaked with material from a lactose broth fermentation tube in which gas has been formed. The medium is best known for this use. Gehm and Heukelekian²¹⁷ reported much success when it was used in this manner. They ran one ml. of inoculum on the surface and spread it over the entire surface of the plate.

Poe²¹⁸ also found considerable merit in eosin-methylene blue agar medium for differentiating *Escherichia coli* from *Aerobacter aerogenes*.

Violet Red Bile Agar. This medium is the result of an attempt to find a solid selective medium for counting coliform bacteria in foods and beverages. Hostettler²¹⁹ found it satisfactory in water analysis. In addition to being more efficient, it gave the coliform bacteria density in actual counts instead of a number based on the theory of probability. The results, obtained in 24 hours, strongly suggest the possibility of using such a direct method. This medium, used by Bartram and Black²²⁰ for isolation of coliform bacteria from milk, was found more satisfactory than several others. Miller and Prickett²²¹ also found it satisfactory as a plating medium. Other investigators have made the same observations on milk and its products. The medium ought to have possibilities with other foods and with water.

Brilliant Green Lactose Bile Agar. This is another medium proposed for estimation of coliform bacteria by direct plating. Noble and Tonney²²³ stressed its advantages and believed that it could replace the liquid brilliant green broth. The results with it were said to be slightly superior to those secured with the liquid medium.

Sodium Citrate-Sodium Ricinoleate Agar. Following development of formate-ricinoleate broth by Stark and England,²²⁴ Littman and Stark²²⁵ attempted to prepare a new plating medium incorporating sodium ricino-

leate. This compound lowers surface tension. Earlier investigators had observed that intestinal bacteria grew well in a medium having a low surface tension, while other bacteria were inhibited. Sodium ricinoleate was used to inhibit gas production of organisms which gave false positive tests. Citrate-ricinoleate agar was said to be a rapid routine test medium for coliform analysis of potable water. Furthermore the much-needed separation of *Escherichia* count from the *Aerobacter* count is now possible with this new agar medium and is available for such examinations as those of shellfish in which major importance is attached to the *Escherichia* count. The authors listed the following advantages of this medium over standard lactose broth: 1. An equal or slightly higher productivity of citrate ricinoleate agar over the standard lactose test. 2. Rapid observation and counting of coliforms possible with citrate ricinoleate agar with a completed count in 24 hours. The time required for the standard lactose test may vary from two to four days. 3. Elimination of false test and synergistic organisms by citrate ricinoleate agar and the elimination of the confirmation of false positive presumptive tests which characterize the standard lactose test. 4. Ability to make differential count between *Escherichia* and *Aerobacter* organisms. 5. Ability of *Eberthella*, *Salmonella*, and *Shigella* to grow on citrate ricinoleate agar with the inclusion of these pathogens among the coliforms in the classification. The standard lactose test fails to detect these organisms. 6. Higher counting accuracy is obtainable by a plating method against a dilution method per tube and plate of media. 7. Use of citrate ricinoleate agar enables a reduction in amount of media, time, and space necessary for routine analysis of water.

Ferrocyanide Citrate Agar Medium of Noble and Tonney. This medium was developed by Noble²²⁶ and Tonney and Noble²²⁷ for direct enumeration by plating of coliform bacteria in water. The advantages of this procedure are obvious. Noble stated that the coliform index of water could be determined in 42 to 48 hours, whereas from three to four days are required by the regular standard methods' technic. Coliform bacteria appear as small pink or brick-red colonies which are distinguishable with ease from other forms. When the medium was used on a large number of samples nearly 77 per cent gave coliform indices which equaled or exceeded those obtained by the standard fermentation method. Noble showed that the productivity or relative efficiency of this medium was superior to those of brilliant green lactose bile broth, and brilliant green lactose bile agar when raw lake water was examined. The various advantages of this medium were reviewed by Tonney and Noble. In addition to those mentioned above, they mentioned the greater accuracy of plating methods over liquid media and the ability to isolate pure cultures. Next Tonney and Noble²²⁷ reported close correlation between the separate count of *Escherichia coli* and probable presence of fecal pollution as indicated by a sanitary survey. The separate *Aerobacter aerogenes* count was

226. Noble. 1928. J. Amer. Water Wks. Assoc. 19, 182-192; 733-746; 23 (1931), 1202-1208; 27 (1935), 1143-1160.

227. Tonney and Noble. 1931. J. Infect. Dis. 48, 413-417; J. Bact. 23 (1932), 473-477.

also uniformly positive in this class of surveys. Nolte and Kramer²¹² found this medium to be unreliable for relatively pure waters. Hoak²²⁸ recommended it although he recognized that it was a little complicated for routine work.

Other media could be used but these just mentioned have received attention from water bacteriologists.

Desoxycholate Agar. This agar-plating medium was devised by Leifson²²⁹ and recommended for direct enumeration of lactose-fermenting bacteria in milk and water. Colonies of these bacteria appear very large and dark red. Colonies of other Gram-negative, non-lactose-fermenting bacteria are either colorless or slightly pink. Colonies of other bacteria are described in the chapter on "Media." Desoxycholate-citrate agar medium considerably inhibits development of *Escherichia coli*.

Brilliant Green in the Presumptive Test. Addition of this dye to the presumptive test medium has been done with the belief that it represses nonconfirming, lactose-fermenting bacteria but allows coliform bacteria to develop and that it, itself, does not inhibit the latter. Many investigations were carried out with it. Muer and Harris,²³⁰ who used a brilliant green broth as a presumptive test medium for *Escherichia coli*, stated that 10 per cent of gas need no longer be regarded as a presumptive test for *Escherichia coli* but a positive test. A dilution of one to 10,000 prevented the development of *Clostridium welchii* and *Clostridium sporogenes*. *Clostridium welchii* was eliminated by a dilution of one to 30,000 while *Escherichia coli* required one to 100. In dilutions of one to 100,000 and one to 1,000,000 in broth, brilliant green in Winslow and Doloffs'²³¹ experiments, inhibited *Escherichia coli*, *Aerobacter aerogenes*, and *Bacterium pneumoniae*. Muer and Harris used brilliant green to accomplish the same results for which Hall used gentian violet. They added ox-gall to the medium and secured a medium which has been studied much since.

This lactose bile-brilliant green medium was found to prevent the development of the anaerobes which cause so much trouble in the presumptive test for *Escherichia coli*. Composition of this medium was studied by Dunham and Schoenlein,²³² who found that it did not show appreciable inhibition of *Escherichia coli*. They, accordingly, studied the concentration of the bile and brilliant green and the optimum hydrogen-ion concentration. A medium containing two per cent of bile, one per cent of peptone, one per cent of lactose, and one to 75,000 brilliant green permitted more rapid development of *Escherichia coli* at pH 6.9 than did the original brilliant green. It was also suggested that the medium should be so prepared that the concentration of ingredients would not be altered when the water sample was added. With large samples of water (10 ml.) double strength medium should be used. McCrady²³³ reported that bile medium almost eliminated all sporeforming, lactose-fermenters. Lauter.²¹⁹ found

that brilliant green bile permitted results several days sooner than the present standard methods. It was also suggested (Dominick and Lauter²³⁴) that methylene blue and brom-cresol-purple could be used to advantage in the lactose broth medium for the presumptive test. Ginter,²³⁵ as did Lauter, emphasized the saving of time which the addition of a low per cent of bile to the presumptive test medium permitted. He could find no evidence that as much bile as five per cent inhibited *Escherichia coli*. Jordan,²³⁶ Ruchhoft,²³⁷ Hale,²³⁸ and Rakieten and Rettger²³⁹ found the medium valuable.

One of the advantages of this medium was said to be elimination of anaerobic, sporeforming bacteria as causes of spurious presumptive tests. This was claimed by Muer and Harris²³⁰ and McCrady.²³³ This was also confirmed by Poe and Witt,²⁴⁰ who reported anaerobes to be inhibited in lactose broth by a content of brilliant green and malachite green greater than one to 10,000; *Clostridium welchii* Type II, however, required a concentration of one to 20,000 before gas formation was prevented. Increasing amounts of bile interfered with the action of the dyes. This inhibition of anaerobes by brilliant green has not been confirmed by Parr and Caldwell.²⁴¹ In their hands, brilliant green bile was not entirely successful with all waters. Butterfield's²⁴² experience was quite similar. Other investigators have found brilliant green bile a good medium; such are Mallmann and Helper,²⁴³ McCrady,²⁴⁴ and Horwood and Heifetz.¹³⁹

Several investigators have stated that brilliant green bile was a more reliable criterion of the presence of coliform bacteria than Standard Methods completed test. Kelly²⁴⁵ made this observation with both water specimens and shellfish samples. If presence of gas in brilliant green bile medium were accepted as sufficient evidence of presence of coliform bacteria, much time would be saved. Taylor²⁴⁶ was of the same opinion as were also Howard, Lochhead, and McCrady.²⁴⁷ Development of *Escherichia-Aerobacter* species was greatly accelerated by addition of .5 per cent of sodium formate to brilliant green lactose bile in experiments by Stark and Curtis.²⁴⁸ This was due to the fact that these organisms can form gas from formic acid. Thus, in this medium the brilliant green acts bacteriostatically against the general flora while sodium formate enhances development of the coliform bacteria.

Some attention must be given to the brand of dye and the amount used. That the brand of dye used may influence the results obtained with bril-

liant green-bile medium was reported by Rakieten and Rettger²³⁹ and Berry and Daniels.²⁴⁹ Different brands and lots of dye were found to vary greatly in efficiency. The amounts used must not be excessive because Coles and Levine²⁵⁰ and Smith²⁵¹ found that growth of microorganisms might be retarded.

Alkyl Sulfates in Standard Lactose Broth. Cowles²⁵² suggested possible addition of alkyl sulfates, in the form of "Drene," to the standard lactose broth medium. Standard lactose broth was used for the basic medium, and to this was added a small amount of an alkyl sulfate. The alkyl sulfates seem to prevent, by and large, the growth of Gram-positive organisms, including the lactose-fermenting aerobes and anaerobes; while the Gram-negatives are, in general, able to develop in the presence of relatively high concentrations of these substances. Sodium lauryl sulfate is the most readily obtained pure compound. To each liter of standard lactose broth .2 gram of the sulfate is added and the pH adjusted to 7.2 before tubing and autoclaving. Ordinary "Drene" shampoo can be substituted in an amount of one ml. per liter, adjusted to pH 7.4. There is some evidence, in fact, that results with "Drene" are better. The finished medium looks like the standard broth, but can easily be distinguished from it by the fact that a lasting foam develops upon shaking, owing to the depressing action of the alkyl sulfate upon the surface tension. As yet insufficient data have been accumulated to permit a definite evaluation of the medium, but the available figures, for the most part, indicate that no inhibition takes place in the growth of the coliform bacteria and that the number of false positives, particularly in the case of finished waters, is decreased very materially. If these results are confirmed in other parts of the country the medium should find a useful place in water analysis. Results with media containing sodium lauryl sulfate were reported by Krasaukas.²⁵³ When this substance was added to lactose broth to the amount of one ml. to the liter, fewer false positive results were secured. While somewhat satisfactory results were also reported by Mallmann and Darby,²⁵⁴ they believed that further investigations were necessary. The selective action was not due alone to lowering of surface tension. Some toxicity to bacteria was shown with the one to 100 concentrations but none in higher dilutions. Hupp²⁵⁵ used this substance to eliminate troublesome aerobic, spore-forming, lactose-fermenting bacteria by incorporating .01 per cent in the broth. Hajna and Perry^{57a} also found lauryl sulfate tryptose broth to yield many more positives for coliform bacteria and to give comparatively few false presumptive reactions.

Gentian Violet Lactose Broth. After Churchman²⁵⁶ had shown that gentian violet in low concentrations was toxic for Gram-positive bacteria,

it was suggested that it might be added to the presumptive test medium to inhibit development of these forms which cause trouble in this test. *Escherichia coli* is a Gram-negative bacterium and would, therefore, not be destroyed. Hall and Ellefson²⁵⁷ found that both the coliform group and the anaerobic group were inhibited by gentian violet in proportion to the concentration and, whereas *Escherichia coli* is not inhibited by a much greater concentration of this dye, its use for the former organism was urged. Addition of one to 100,000 gentian violet to lactose broth inhibited 94.5 per cent of the spurious presumptives; one to 20,000 increased this inhibition to 95 per cent. This work was confirmed in the laboratories of the Illinois State Water Survey by Wagner.¹⁶⁴ She stated that a medium containing two per cent of peptone, .2 per cent of lactose, and .001 per cent of gentian violet, when used with an equal volume of water, gave superior results to those secured by using the standard .5 to .1 per cent carbohydrate broth. Wagner (Mrs. Stearn)²⁵⁸ reported a later investigation to determine whether the modified lactose gentian violet broth showed any inhibitory action on *Escherichia coli* and other lactose-fermenting bacteria. She reported that culturing *Escherichia coli* in gentian violet broth, brought about an increase in fermentative activity, motility, and growth rather than a decrease. Winslow and Dolloffs²³¹ found an appreciable germicidal action of gentian violet in ordinary broth media. Its activity in this respect was greatly reduced in the presence of bile salts. Furthermore, they reported that the inhibitory properties of gentian violet depended on the medium in which it was placed. Salle²⁵⁹ considered it unfortunate that gentian violet was ever used in bacteriological media to restrict the growth of certain organisms. Gentian violet is a term which does not refer to a definite chemical compound, but rather to a mixture of dyes of a certain group. Since crystal violet, one of the important constituents of gentian violet, has a definite chemical formula, he suggested that crystal violet be designated instead of gentian violet. Salle, therefore, proposed a crystal violet broth medium for the presumptive test in water analysis. Production of acid and gas in this medium in practically all of the samples examined was found to be due to members of the colon-aerogenes group. An agar-dye differential medium was also reported with which *Escherichia coli* could be differentiated from *Aerobacter aerogenes* because of distinct differences in metabolism of carbohydrates. The amount of lactose used in this medium was so gauged that *Escherichia coli* produced its maximum acidity; this amount was inadequate for *Aerobacter aerogenes* to produce its limiting hydrogen-ion concentration. *Escherichia coli* produced brilliant metallic colonies, slightly raised, with the color of the surrounding medium changed from purple to an orange tinge. *Aerobacter aerogenes* forms colonies which tend to flow together; there is no change in the color of the surrounding medium. Stark and England²⁶⁰ reported, however, that Salle's medium should not be used because it

inhibited fecal organisms. When it was inoculated with a pure culture of *Escherichia coli* from fresh feces and incubated at 37° (98.6°F.), 43 per cent of the tubes were negative after 48 hours' incubation while parallel inoculations in lactose broth gave positive results in all cases. If, however, the tubes were held for about five days, gas formation occurred. These results seem to indicate that *Escherichia coli* might be initially inhibited. Especially significant is the absence of gas formation in the first 48 hours. In a latter paper Stark and Curtis²⁴⁸ confirmed these results. Salle's crystal violet broth, Dominick and Lauter's broth, gentian violet broth, and brilliant green bile (two per cent) broth were studied. Crystal violet, methylene blue, gentian violet, and brilliant green were found to be growth inhibiting. Shunk²⁶¹ also observed inhibition of small numbers of *Escherichia coli*.

Uric Acid Medium for the Presumptive Test. Among the many other media for use in the presumptive test for *Escherichia coli*, uric acid as the sole source of nitrogen in a medium was proposed by Koser.²⁶² Using 74 strains of *Escherichia coli* and 50 strains of *Aerobacter aerogenes*, he found a selective action since the *Aerobacter aerogenes* grew well. The uric acid medium, also used by Rettger and Chen²⁶³ and Perry and Monfort²⁶⁴ to make the same separation, produced the same results. Bardsley²⁶⁵ reported that Koser's uric acid test gave imperfect correlations with other tests for *Escherichia coli*. Similar observations were reported by Lind²⁶⁶ who tested 87 strains of *Escherichia coli* isolated from human feces. Satisfactory correlation was found between citrate, indol, methyl-red, and Voges-Proskauer tests, but none between these and the uric acid tests. Thus while most of the strains tested failed to grow upon citrate medium, 38 out of 88 grew well upon uric acid medium.

Cellobiose Fermentation as Presumptive Test. Jones and Wise²⁶⁷ suggested use of cellobiose for sharply differentiating the genus *Escherichia* from *Aerobacter*. Cellobiose is a glucoside produced from cellobiose octaacetate, which is prepared from cotton cellulose or filter paper. The process of conversion must be carefully and accurately carried through to obtain a pure cellobiose. Cellobiose has not been used for practical bacteriological work; though it is rapidly utilized by *Aerobacter aerogenes* with gas and acid production, no changes are made by any strains of the *Escherichia coli* examined by the authors. A .5-per cent cellobiose was added to the nutrient broth, tubed, and sterilized by autoclaving 20 minutes at 120°C. (248°F.). Results were observed at 12, 24, and 120 hours, respectively. All known strains of *Aerobacter aerogenes* split cellobiose with gas and acid production, while *Escherichia coli* did not. These results are correlated with the Voges-Proskauer test. Koser²⁶⁸ subjected

the cultures of his collection of coliform strains of bacteria to the cellobiose fermentation, and reported a striking correlation between the two well-defined sections of the group. However, the so-called intermediate strains did not exhibit this correlation.

According to Poe²⁶⁹ and Poe and Klemme²⁶⁹ the cellobiose test did not give a satisfactory correlation with the methyl-red and Voges-Proskauer reactions for coliform bacteria. The correlation for *Aerobacter aerogenes* was almost perfect.

Ratio of carbon dioxide to hydrogen was from .3 to .5 in gas produced from cellobiose by *Escherichia* strains. With *Aerobacter* and *Aerobacter cloacae*, ratio was close to .7. Cellobiose-negative strains of *Escherichia* which produced no gas did not ferment all cellobiose in .1 to one per cent solution in 72 hours at 37°C. (98.6°F.). Those which formed gas and the *Aerobacter* strains fermented it completely under the same conditions. With both groups of organisms in medium containing .1 per cent sugar, pH values reached minimum in about 12 hours and then increased to maximum of about 8.5. Minimum for cellobiose-negative organisms was not as low as for cellobiose-positive. Though difference in amounts of products formed by the two groups was slight, *Aerobacter* formed somewhat more succinic and lactic acids than did *Escherichia*.

After modification of the cellobiose broth of Jones and Wise, by reduction of the cellobiose to .25 per cent, Dowd²⁷⁰ secured better results. Cost was reduced by tubing in small tubes requiring only one ml. of medium. Gas and acid formation were rapid and definite and sufficient study was made to indicate an excellent correlation with several other differentiating media in the two well-defined sections of the group. Correlation was especially good with known source of the culture and with results of Koser's citrate test. Tittsler²⁷¹ tested ability to ferment cellobiose of 755 cultures, representing approximately 50 species in various genera. Acid and gas were produced by *Aerobacter* cultures and most *Escherichia*-*Aerobacter* "intermediates" but not by typical *Escherichia* cultures. All strains of *Eberthella typhosa*, *Salmonella aertrycke*, and *Salmonella schottmülleri* and 17 of 19 strains of *Salmonella enteritidis* attacked cellobiose after four to 10 days, whereas all strains of *Salmonella suipestifer*, *Salmonella paratyphi*, *Salmonella gallinarum*, *Salmonella pullorum*, *Salmonella morgani*, and of dysentery bacilli failed to do so within 14 days. These results indicate that cellobiose fermentation might be of value in the *Proteus* and *Salmonella* group.

CITRATE (CITRIC ACID) FERMENTATION

This method has enjoyed the confidence of water bacteriologists. Koser²⁷² devised the test after observations made on utilization of the salts of organic acids by coliform bacteria. These organic acids were added to a synthetic medium in the form of their sodium salts. Striking

results were obtained with citric acid. Fecal *Escherichia coli* failed to develop while *Aerobacter aerogenes* produced luxuriant growth. While sodium citrate was used, Koser reported identical results with ammonium or potassium citrate. In his next report, Koser confirmed his former work. He collected cultures from various sources, keeping careful record of their history and source. One hundred and eighteen were obtained from fecal specimens and 72 from soils as far removed as possible from sources of pollution. Koser applied his uric acid and citric acid tests to these organisms and also the methyl-red and Voges-Proskauer tests of "standard methods." With these strains Koser also found that *Escherichia coli* of fecal origin was unable to utilize sodium or potassium citrate when supplied as the sole source of carbon, whereas the aerogenes-cloacae types, which represented the largest section of the soil cultures, all utilized citrate readily. As others have found, when differentiating members of the coliform group by different tests, Koser found "intermediates" which did not fall clearly into one or the other groups. These discrepancies occurred chiefly among the soil cultures. He had 23 soil strains which were consistently methyl-red positive and at the same time developed in the citrate medium. These organisms were proposed as constituting another section of the colon-aerogenes group which could be differentiated from fecal methyl-red positive type by utilization of citrate. Their presence in soil and apparent absence from fecal specimens constitutes evidence that not all of the methyl-red positive colon group organisms encountered in nature are of fecal origin. In a later paper, Koser reported that the citrate test correlated somewhat with the sanitary survey. Ability to utilize citrate also seemed to be a permanent characteristic and one not easily acquired or lost. Koser's work was nicely confirmed by Pawan,²⁷³ working in Trinidad.

Murray and Skinner,²⁷⁴ in isolating iron bacteria, used Harder's medium consisting of inorganic salts among which was ferric ammonium citrate. They were interested in trying *Escherichia coli* and comparing the results with Koser's citrate medium. They found a good correlation. In the Koser solid medium in which ferric ammonium citrate replaced the sodium citrate, good differentiation of organisms was possible.

Experiments were carried out by Koser to determine whether dicarboxylic and tricarboxylic acids could be used for separating *Escherichia coli* from *Aerobacter aerogenes*. Although several of these acids are structurally similar to citric none of them gave the same separation that citric acid gave. Koser²⁷⁵ reviewed the literature which had been published on comparisons of the methyl-red, Voges-Proskauer, and citrate differentiation reactions. In general, it was shown that the citrate test gave good differentiation between *Escherichia coli* and *Aerobacter aerogenes*.

Observations by Taylor *et al.*²⁷⁶ indicated that the results of the citrate fermentation test correlated well with sanitary inspection. Hicks¹⁷⁵ also

found Koser's medium to differentiate lactose-fermenting bacteria from polluted and unpolluted sources, as did Ruchhoft *et al.*²⁷⁷ In the hands of Poe²¹⁸ correlation between the Voges-Proskauer and methyl-red tests, and the citrate test of Koser was almost perfect for the *Aerobacter aerogenes* section and 77 per cent perfect for the *Escherichia coli* section. That the results of the citrate test correlate well with those of the Voges-Proskauer and methyl-red tests was also reported by Hoak.²⁷⁸

Results of investigations by Kline²⁷⁹ seem to indicate that *Escherichia coli* may acquire the ability to utilize citrate as the sole source of carbon. A carefully purified culture of this organism was introduced at one end of a 20-foot stovepipe filled with sterile soil. Sterile water was introduced at the head of the pipe and allowed to seep slowly through the soil. Samples of the soil were withdrawn from different parts of the pipe at intervals up to 400 days after inoculation. Altogether 726 strains were isolated and typed. During the first 100 days of the experiment the great majority of strains isolated were typical *Escherichia coli*, but after this time atypical strains began to appear frequently. No fewer than 75 cultures (10.3 per cent of the total) isolated after the 95th day proved to be citrate-positive. According to Parr and Simpson²⁸⁰ some coliform bacteria may not readily utilize citrate. Coliform "mutants" were observed which persistently refused to grow on citrate agar.

A modification of Koser's citrate medium was made by Simmons²⁸¹ who added two per cent of agar and brom-thymol-blue to give a solid medium. Use of this solid medium obviates the use of turbidity as a criterion of growth. The medium may be used either as a slant or in Petri-dish cultures. *Aerobacter aerogenes* grows luxuriantly; *Escherichia coli* does not grow at all or so sparsely that no color change occurs in the medium. Another modification was reported by Perelli²⁸² as follows:

Two grams of agar are dissolved in 100 ml. distilled water in an autoclave; .25 per cent sodium citrate is added and the flask shaken until it is completely dissolved. Then .5 per cent picric acid solution (one per cent), two ml. of a .2-per cent solution of malachite green, and .5 ml. of a 1.5-per cent alcohol solution of brom-thymol blue are added. The mixture is shaken and distributed without sterilization into tubes and plates. The colon bacillus develops in this medium but leaves the color unaltered. *Aerobacter aerogenes* forms dew-drop colonies and turns the medium completely blue within 24 hours at 37°C.(98.6°F.). Harry²⁸³ preferred the Simmons' modification of the citrate medium.

Considerable study has been given to the citrate test by the Metropolitan Water Board of London in its Thirty-Second Annual Report for the year 1937. Results of many investigations were reported. In general the citrate test has continued to yield satisfactory results. In the Thirty-Third

Annual Report for 1938, the test was modified by addition of brom thymol blue to the medium so that growth was indicated by a color change from apple green to blue. Occasionally specimens were analyzed which did not appreciably alter the color of the medium while growth was shown by a heavy deposit. Fortunately such specimens were rare and were confined only to one or two sources. The test was introduced into the routine confirmation of coliform types from presumptive tubes and differentiated between *Escherichia coli* and intermediates. In spite of much previous work, some of which has just been reviewed. Stark and Straughn²⁸⁴ stated that the utilization of citrate as the sole source of carbon is an unreliable and unjustifiable characteristic for differentiating the genera *Escherichia* and *Aerobacter*. They confirmed the validity of the methyl-red test, the Voges-Proskauer reaction, and the gas ratio for this purpose.

The Eijkmann²⁸⁵ Test for Differentiating Coliform Bacteria. This method, proposed in 1904 by Eijkmann, was supposed to differentiate coliform bacteria from warm-blooded animals from strains of those from cold-blooded animals. It consists in the main of inoculating fermentation tubes containing dextrose broth with the samples and incubating at 46°C. (114.8°F.). The higher temperature of incubation was supposed to eliminate non-fecal strains and permit development of fecal strains. The method has been subjected to much study with conflicting and contradictory results. Among those who found the test satisfactory are Christian,²⁸⁶ Neumann,²⁸⁷ Thomann,²⁸⁸ Hilgerman,²⁸⁹ de Graaff,²⁹⁰ and Van Hoytema.⁹¹ Those who did not find it to be satisfactory were Nowack,²⁹² Konrich,²⁹³ and Sachse.²⁹⁴ Several of the latter based most of their objections on the fact that fecal coliform bacteria might be inhibited. Results of investigations by these earlier investigators will not be reviewed in order to consider more recent studies. Results of investigations are not always in agreement and consequently bacteriologists differ in their attitudes toward the test. More recently it has been found that the temperature must be carefully controlled. We may wonder whether this was always appreciated by the earlier investigators who have condemned the test.

Comparison of the Eijkmann test with the methods in *Standard Methods for the Examination of Water and Sewage*, by Leiter,²⁹⁵ revealed some interesting facts. The investigation involved a number of questions, which were raised in connection with the test. Leiter concluded that the Eijkmann fermentation test, as applied to water, was selective for *Escherichia coli* through the inhibition of other organisms. He observed close relation

between indol formation and fermentation of Eijkmann's medium. Other findings seemed to be favorable to the Eijkmann test. Leiter stated that it possessed some features which made it preferable to "standard methods" then in use. It is more rapid, requiring only 16 to 24 hours, and permits a higher percentage of positive tests. Positive Eijkmann tests infrequently yielded members of the *Aerogenes-Cloacae* group, whereas *Standard Methods* technique yielded them frequently. Brown and Skinner²⁹⁶ found little merit in the Eijkmann test, as did Wagner.²⁹⁷

As would be expected, some strains of *Escherichia coli* have been found to be inhibited at 46°C.(114.8°F.). Barth²⁹⁸ claimed that strains from cold-blooded animals would not grow much above 37°C.(98.6°F.). Magalhaes²⁹⁹ secured results with the Eijkmann test quite like those of Leiter. He stated that in the majority of cases *Escherichia coli* from cold-blooded animals did not attack sugars at 46°C.(114.8°F.), while strains from warm-blooded animals cause fermentation with gas production. Only a small percentage of *Escherichia coli* from human feces produced gas, according to Brown and Skinner,²⁹⁶ which contradicted the above statement of Magalhaes. Many strains produced gas in 24 hours in the Eijkmann test, but 48 hours were necessary to include all gas formers. Many "typical" *Escherichia coli* strains from water from a polluted stream failed to grow in the Eijkmann broth at 46°C.(114.8°C.). The Eijkmann test did not eliminate all positive results caused by *Aerobacter aerogenes* and citrate-positive *Escherichia coli*. Only *Escherichia coli* (never *Aerobacter aerogenes*) was found in human feces.

Skinner and Brown³⁰⁰ reported that the Eijkmann and the Bulir³⁰¹ tests (glucose and mannitol broth, respectively, at 46°C.) detected significantly fewer *Escherichia coli* than did the usual method using lactose broth at 37.5°C. To a less degree, but still significantly, this was true when the 46°C. of the Eijkmann and Bulir methods was reduced in five hours by a gradual increase in temperature. Partial explanations for the conflicting results on the Eijkmann test, found in the literature, were proposed. Possibly the large amounts of media used by some investigators allowed some of the coliform bacteria to adapt themselves to a gradual increasing temperature. It was suggested that the Bulir test has a possible slight advantage over the modified Eijkmann test. A similar but smaller advantage of the modified Bulir over the modified Eijkmann test is thought possible. This latter supposition, however, was not shown statistically by the data, based on over 4,500 inoculations. Necessity of rather heavy inoculations with the Eijkmann test was shown by Minkevich *et al.*³⁰² He concluded that 46°C. is the maximum temperature at which *Escherichia coli communis* will grow; it invariably grows at this temperature only when massive inoculations are employed; it frequently fails to grow if the

inoculation is not massive; if the incubation temperature is reduced to 43 to 43.5°C. (109.4°F.), even single-cell inoculations of *Escherichia coli communis* will demonstrate their presence.

They recommend the following procedure for obtaining the coli content of water: (1) test in Bulir's media at 43 to 43.5°C.; (2) transfer last two dilutions showing gas to Endo or E.M.B.; (3) transfer appropriate colonies from solid media to Bulir's media, massive inoculation, for incubation at 46°C. (114.8°F.). The authors state that this procedure obtains all *Escherichia coli communis* and "absolutely excludes *Bacterium aerogenes*, *Bacterium cloacae*, *Bacterium aquatilis*, *communis* and coliform varieties from the intestines of cold-blooded animals."

The original Eijkmann test required glucose as the carbohydrate; Perry and Hajna³⁰³ and Hajna and Perry³⁰⁴ studied other sugars. Hajna³⁰⁵ reported an investigation in which the action of bacteria of the genus *Escherichia* on seven monosaccharides (arabinose, xylose, glucose, mannose, fructose, galactose, rhamnose), four disaccharides (lactose, sucrose, maltose, trehalose), and four alcohols (mannitol, dulcitol, sorbitol, and adonitol) at 37°C. (98.6°F.) and 46°C. (114.8°F.) were studied. Buffers enhanced gas production at both 37°C. and 46°C. In a well buffered basic medium all sugars and alcohols tested, except dulcitol and adonitol which were never fermented with gas at 46°C. (114.8°F.), were readily decomposed at both temperatures. In an adequately buffered medium, all the bacteria used remained viable after an incubation period of 72 hours. Gas production was likewise influenced greatly by the type of protein in the medium. Perry and Hajna³⁰³ previously reported that more *Escherichia coli* were recovered from feces with "Standard Methods" lactose broth than with original Eijkmann medium at 46°C. (114.8°F.); but the reverse was true when the latter was modified by buffering with .4 per cent of di-potassium hydrogen phosphate and using .3 per cent of glucose instead of 1.4 per cent. *Escherichia coli* cultures in old medium were seldom viable after 24 hours incubation at 46°C. but in new medium all were viable 118 hours or longer. Tests showed that ability to ferment glucose at 46°C. is a fundamental characteristic of *Escherichia coli* as stated by Eijkmann. Hajna and Perry construe *Escherichia coli* to include only those members of the coliform group which invariably ferment glucose at 46°C. in suitable medium and are unable to utilize citrate carbon. The importance of Eijkmann test in water analysis is stressed. Further work by Hajna and Perry³⁰⁶ led them to prefer for separation of fecal *Escherichia coli* from other coliform organisms the use of their modification of the Eijkmann medium in an air incubator at 45.5 to 46°C. (114.8°F.). Their medium contained 1.5 per cent of peptone, .3 per cent of lactose, and buffer salts. In tests made with Eijkmann media containing glucose, lactose, or mannite at temperatures of 42, 44, and 46°C. (107.6, 111.2, and 114.8°F.), all of 1,374 *Escherichia coli* strains produced gas at 46°C. from

mannite, while four and five strains, respectively, (all from raw sewage) failed in glucose and lactose. Few *Escherichia coli* strains produced gas at 46°C., but many did at the lower temperatures. Strains of *Aerobacter cloacae* and intermediate types frequently grew also at 44°C. but rarely at 46°C., and did not produce gas in glucose or lactose at the latter temperature. In parallel tests of their own medium and that of MacConkey in an air incubator and a water bath at 44°C., all of 66 *Escherichia coli* strains of human origin were positive in the modified Eijkmann medium, while two failed in air and 16 in the water bath in MacConkey's medium. Many *Aerobacter aerogenes* strains produced gas at 44°C., fewer, however, in MacConkey's medium. Both media were satisfactory for suppression of *Aerobacter cloacae* and intermediates under both conditions of incubation. It is claimed that isolation of coliform organisms is easy after growth for three days in Eijkmann's medium at 44°C., but difficult from MacConkey's even after 48 hours.

Results of more recent experiments have led investigators to opposite conclusions. Raven, Peden, and Wright,³⁰⁷ Taylor and Goyle,³⁰⁸ and Ferramolo and Monteverde³⁰⁹ were favorable while Webster and Raghavachari³¹⁰ were not. These discrepancies may be due to lack of accurate control of temperature of incubation, as was stated by Clegg and Sherwood³¹¹ who supported their contentions with many data. This is a difficult situation to comprehend.

The Metropolitan Water Board of London has carried out many investigations, results of which are reported in its annual reports for years before and after 1940. Their results were not especially favorable to this method as a routine procedure. The test as they carried it out seemed to give erratic results. Eijkmann's method has been used also for determining the quality of oysters and nut meats.

When applied to detection of the presence of *Escherichia coli* in nut meats, Ostrolenk and Hunter³¹² found the Eijkmann test to be unreliable. Although it surpassed standard lactose broth in limiting development of *Aerobacter* and *Citrobacter*, it reduced development of *Escherichia*.

Neutral Red in the Presumptive Test. The use of neutral red lactose broth in water analysis was proposed by Rothberger.³¹³ After experimenting with various dyes, he noticed that *Escherichia coli* turned neutral red medium red, while *Eberthella typhosa* caused no change. This change in color was believed to be sufficiently specific for practical application. As might be expected, various investigators tried to confirm Rothberger's conclusions. Irons³¹⁴ and Gage and Phelps³¹⁵ were unable to do so. On the

other hand, Makgill,³¹⁶ Savage,³¹⁷ and Stokes³¹⁸ considered the method to be a delicate one for determining the presence of pollution in water. Chamot and Sherwood³¹⁹ attempted to improve the medium and make it more reliable. They arrived at a formula which they believed gave a more suitable medium than lactose bile. Georgia and Morales,³²⁰ after analyzing 185 samples of water, stated that neutral red medium was better than any medium yet proposed for a presumptive medium for *Escherichia coli*.

Concentration Methods for Coliform Bacteria. Coliform bacteria may not be abundant in some waters which have received pollution and may be lost during the tests designed to determine their presence. They may be concentrated in small amounts of water which may be subjected to routine examination. Edington³²¹ used the Seitz filter, Schulkoff and Heukelekian³²² the centrifuge. The latter investigators showed that results of examination of specimens prepared in this manner were satisfactory indices of quality. Their investigation is quite pertinent just now in view of the desire to use larger samples in the Treasury Department procedure. Zeetti³²³ adapted a method previously reported by Rasumov.³²⁴ Thin cellulose membrane was employed in infiltration of water and then placed on solid medium in a Petri dish, with surface, which was in contact with water, turned up. During the period in the thermostat, bacteria on cellulose membrane grew in colonies, as they would on underlying medium. After growth of bacteria, the membrane was examined microscopically.

LONGEVITY OF *ESCHERICHIA COLI* AND *AEROBACTER AEROGENES*

This is an important question in relation to the significance of these organisms in sanitary water analysis. Exact knowledge on the question, if it may ever be secured, would determine the significance of results of certain procedures in water analysis.

In Water: Longevity of *Escherichia coli* in water has much to do with its value as an indicator. Rogers³²⁵ found that *Aerobacter aerogenes* was more resistant than *Escherichia coli*. During long periods of storage, its percentage gradually increased. In a later investigation Rogers artificially infected water with feces and held it at 20°C. (68°F.). At the end of nine months the relative numbers were reversed. There were 39 *Aerobacter aerogenes* to one of *Escherichia coli*. In sewage stored in running water there was more rapid decrease in *Escherichia coli* than *Aerobacter aerogenes*. At the beginning there were about three times as many *Escherichia coli*, but after seven days, there were a few more *Aerobacter aerogenes*. Greer and Nyhan³²⁶ found that in mixtures of two

326. Greer and Nyhan. 1928. J. Infect. Dis. 42, 525-536.

bacteria in a medium which each could use, there was a tendency for one to gain ascendancy over the other. The experimental work of these investigators indicated that *Escherichia coli* may be overgrown by *Streptococcus fecalis*, *Clostridium welchii*, and *Pseudomonas pyocaneus* in 48 hours. Experiments along this same line were reported by Teissier and Couvier³²⁷; bacterial examination of water which had been collected for 20 years, taken in sterile bottles and kept in the dark, showed that ordinary saprophytic bacteria had died out while *Escherichia coli* remained viable and grew well when placed under favorable conditions.

The viability of organisms inoculated into water taken from the open sea and into sewage contaminated sea water was as follows in Trawinski's³²⁸ experiments:

	Uncontaminated sea water	Contaminated sea water
<i>Salmonella schottmülleri</i>	12 days	12 days
<i>Salmonella schottmülleri</i> (Breslau).....	12	7
<i>Salmonella schottmülleri</i> (Gaustedt).....	16	16
<i>Salmonella enteritidis</i>	23	4
<i>Salmonella paratyphi</i>	18	6
<i>Eberthella typhosa</i>	16	3
<i>Eberthella dysenteriae</i> (Shiga).....	12 hours	30 hours

According to Jones³²⁹ *Escherichia coli* dies out during storage, more rapidly in the tropics and more slowly on voyages through cooler seas. Cleaning or "cement-washing" the storage tanks exerts no influence. The results of an investigation by Platt³³⁰ of the influence of temperature, aeration, and light on survival of these two bacteria in water showed that (1) both organisms survived longer in sterilized than in raw river water; (2) they died out rapidly at 37°C.(98.6°F.) but survived for several weeks at 0°C.(32°F.); (3) if water kept at room temperature was shaken occasionally, actual multiplication of the organisms occurred owing to the beneficial effect of aeration; (4) the organisms survived longer at room temperature when kept in the dark than in daylight; (5) at 0°C. and 37°C. coli and aerogenes proved of much the same degree of resistance, but at room temperature 18 to 20°C.(64.4 to 68°F.) aerogenes survived considerably longer than coli. The general conclusion was that under ordinary environmental conditions *Aerobacter aerogenes* is likely to survive longer in raw water than *Escherichia coli*. Observations made with coliform bacilli of various types by Bigger³³¹ showed that in autoclaved waters multiplication occurred to a variable, and often considerable, extent in flasks incubated at 22°C.(71.6°F.) or 37°C.(98.6°F.). Growth frequently occurred in waves. In raw waters, on the other hand, multiplication was practically never observed and the organisms gradually died off. Numerous attempts were made to explain these facts. It was found that heating to 60°C.(140°F.) for one hour, filtration, or adsorption with kaolin

or charcoal, rendered raw water quite suitable for growth of coliform bacilli, though not all waters behaved alike and several irregularities were met. Evidence was brought to show that the waters used contained enough nutritive material to support the growth of coliform bacilli, but that some inhibitory substance present in raw water, removed by autoclaving or one of the other treatments just mentioned, prevented their growth. It was therefore concluded that carbon dioxide destroyed its ability to support growth, and it is therefore concluded that carbon dioxide is probably responsible for the prevention of growth in raw water. These results are in accord with those reported by Platt, although the latter explained the wavy growth as being due to the beneficial action of oxygen which gained access to the flasks when they were intermittently shaken.

Much study has been given longevity of coliform bacteria in the laboratories of the Metropolitan Water Board of London.³³² In samples in which there was good development of saprophytes, the inoculated coliform bacteria disappeared after two to three weeks. Some coliform bacteria increased slightly in samples devoid of saprophytes. It would appear that the viability of coliform organisms is influenced by the presence and multiplication of saprophytic survivors, and the extent to which these prevail depends largely upon the efficacy of the initial process of disinfection employed. Further experiments are being devised in extension of this investigation, since undoubtedly a variety of other contributory factors exist.

Longevity studies of coliform bacteria in nature by Tonney and Noble³³³ have thrown much light on this entire problem which is of considerable importance in interpreting results of laboratory examination in sanitary work. Under winter conditions *Escherichia coli* and *Aerobacter aerogenes*, both from fecal material and from cultures, underwent rapid decline without exhibiting significant change in relative numbers. At no time was there a material difference in surviving time of either type of organism in feces. The rather marked relative increase in growth of *Aerobacter aerogenes* over *Escherichia coli* occurring in certain culture plantings suggests the possibility that the commonly observed predominance of *Aerobacter aerogenes* in nature may be due in part to greater multiplication of certain hardy strains. Under such circumstances, the *Aerobacter aerogenes* count, if accepted as a quantitative index of fecal pollution, would tend to distort the sanitary picture, yielding no evidence of the recency of contamination, and giving an exaggerated idea of the amount of pollution after two months, at which time pollution is less dangerous from the standpoint of water-borne disease than at the outset. The coliform count, on the other hand, had a more consistent relation to initial amount of fecal pollution and to time elapsing after its occurrence, both of which factors are of essential importance in judging dangerous pollution. The high resistance of the colon-aerogenes group to action of the elements was evident, and gives further assurance that as test organisms,

332. Thirteenth Ann. Rept. Metropolitan Water Board, London.

333. Tonney and Noble. 1931. J. Bact. 22, 433-446.

their survival time affords a safe margin over that of the less resistant intestinal pathogens which constitute the real danger from fecal pollution. The plate-count method in ferrocyanide citrate agar was a sensitive measure of changes in numbers of coliform organisms under the test conditions. The fact that *Escherichia coli* and *Aerobacter aerogenes* live a long time in wood under natural conditions, has a practical bearing on the quality of water from any supply in which the water is in contact with wood. Wooden storage tanks are often used, especially in small supply systems. In older types of private wells, wooden casings are commonly used and sometimes wooden troughs or conduits as well. There also still remain a few "old oaken buckets." Under such conditions, presence of aerogenes alone would be of no sanitary significance.

In Sewage: The end desired in sanitary water analysis is knowledge with respect to safety of a water supply. Modern laboratory practice rests on determination of the presence of certain organisms indigenous to sewage, in the water. If the organisms which are used as indicators of pollution are short-lived in either sewage or water, the test has serious limitation. To determine the effect that natural purification processes might have on disappearance of *Escherichia coli* and *Aerobacter aerogenes*, Ruchhoft and Coulter³³⁴ made a bacterial survey of samples ranging from raw sewage of Chicago plants to water from points in the Illinois river for about 125 miles below Lockport. In all cases inoculation ensued into standard lactose broth and on Noble medium within four hours after collection. Growth on eosin methylene-blue plates and subsequent gas formation in brilliant green tubes were used to confirm lactose presumptives. Direct plate counts gave lower, and probably more accurate, *Escherichia coli* densities. Conclusion is that self-purification in streams, including dilution, effects little change in ratio of *Escherichia coli* to *Aerobacter aerogenes* from that pre-existing in sewage; necessity for their differentiation is therefore slight.

The degree of contamination seems to have much to do with the survival time of various bacteria. Rochaix³³⁵ sterilized sewage which was free from industrial wastes and inoculated it with various pathogenic bacteria. The samples were held at room temperature for frequent examination. In one experiment *Eberthella typhosa*, *Salmonella paratyphi*, *Salmonella schottmülleri*, *Vibrio comma*, and *Pseudomonas aeruginosa* were alive after seven months and 14 days; *Salmonella schottmülleri* and *Pseudomonas aeruginosa*, at the end of 20 months and eight days.

In other experiments *Vibrio comma* and *Eberthella typhosa* survived in sterilized sewage water only three months and seven days, while in sterilized distilled water they lived for six months and 23 days; in a fourth experiment *Salmonella schottmülleri* survived for 112 days in sterilized sewage, while in sterilized distilled water it lived for eight and one-half months. In the remaining four experiments *Salmonella schottmülleri*, *Vibrio comma*, and *Eberthella typhosa* were tested in sterilized sewage

334. Ruchhoft and Coulter. 1933. J. Bact. 25, 431.

335. Rochaix. 1930. Ann. Hyg. Pub. Indus. et Soc. 8, 669-675.

water, survival of each by itself being compared with its survival in a mixed culture of saprophytic organisms. In each case, the pathogenic organism lived longer in pure than in mixed culture, and in mixed culture the saprophyte survived the pathogen. These results indicate that, while sewage is in itself a good culture medium for pathogenic organisms, the "vital concurrence" of saprophytes must play a large part in the disappearance of the pathogens. Results of a similar investigation were reported by Heukelekian and Schulhoff.³³⁶

In Soil: Less is known about survival of coliform bacteria in soil than in water or sewage. Tonney and Noble³³³ planted *Aerobacter aerogenes* cultures in decayed stumps without admixture with fecal material, after which plate counts were made until the organisms disappeared. After about 60 days, increase of *Aerobacter aerogenes* was considerable while *Escherichia coli* increase was only slight. From this Tonney and Noble stated that excessive concentrations of *Aerobacter aerogenes* might give a distorted sanitary picture with little evidence of fecal pollution. This was the case at the time when their paper was written; now however, when less importance is given to separation of *Aerobacter aerogenes* from *Escherichia coli* with the significance which was formerly given, these conclusions have less weight. Skinner and Murray³³⁷ found little difference between *Escherichia coli* and *Aerobacter aerogenes* as regards longevity in soil. Both organisms disappeared from soil inoculated with manure after 150 to 200 days.

According to Minkevich and Rabinovich,³³⁸ *Escherichia coli* is able to adapt itself to conditions in the soil. All soil strains are evolved from the fecal type. Isolation of strains capable of assimilating citrate in water and other materials before the lapse of six months is without epidemiological significance so far as fecal contamination is concerned because pathogenic bacteria of the typhoid group perish in that period of time.

UNITED STATES PUBLIC HEALTH SERVICE STANDARDS OF PURITY FOR DRINKING WATER (TREASURY DEPARTMENT STANDARDS)

About 1914, the United States Public Health Service suggested that the quality of water served the traveling public on common carriers needed attention. The results of this suggestion was the formulation by a committee of sanitarians of a procedure for examination of such waters and a set of standards. The first standards will not be included in this book.³³⁹

They were applied to the examination of water from trains by Bartow,³⁴⁰ Creel,³⁴¹ Hanford,³⁴² and to water from boats by Cobb, Williams, and Letton.³⁴³ Bartow confirmed the presence of *Escherichia coli* in 83 per cent of the samples examined. Creel found that an anaerobic bacillus which formed gas was responsible for gas in the presumptive test in 91

out of 421 samples. Such data indicate the significance of the confirmatory test. More data are required before it may be determined whether this method is the best. Letton³⁴⁴ later stated that the requirement of "not more than 100 colonies per milliliter on agar" of the Treasury Department standard was very lenient. He regarded the limit of permissible *Escherichia coli* (not more than two per 100 ml.) as not too low.

Considerable attention was given to this subject after the first proposed standard had been formulated and used. Gorman³⁴⁵ gave advice on methods to be followed for taking the water. Connolly and Gorman³⁴⁶ showed that a marked decrease had occurred in typhoid fever among seamen. Even as late as 1938, undesirable conditions existed on cars of some railroads. Miller and Garthe³⁴⁷ found water to be handled in an unsanitary fashion without sufficient cleaning of water tanks.

In May, 1922, the Surgeon General of the United States Public Health Service appointed another committee to formulate definite specifications which could be used by the Public Health Service for controlling water supplied for drinking and culinary purposes on interstate carriers. The committee [Pub. Health Repts. Pt. 1, 40 (1925) 693-710] was loath to accept any one criterion. They recommended that the bacteriological standard outlined below be applied with same latitude. For instance, supplies which, on rigid inspection, are found to be satisfactory in other respects but fail to meet the bacteriological standard, may be accepted in the discretion of the certifying authority. This suggestion avoided some of the difficulties which arose in the application of the old standard.

STANDARDS

I. AS TO SOURCE AND PROTECTION

1. The water supply shall be—

- (a) Obtained from a source free from pollution; or
- (b) Obtained from a source adequately protected by natural agencies from the effects of pollution; or
- (c) Adequately protected by artificial treatment.

2. The water supply system, including reservoirs, pipe lines, wells, pumping equipment, purification works, distributing reservoirs, mains, and service pipes, shall be free from sanitary defects.

NOTE. 1. *Natural agencies* affording more or less complete protection against the effects of pollution are, in surface water: dilution, storage, sedimentation, the effects of sunlight, and the associated biological process tending to natural purification; and, in the case of ground waters, percolation through the soil. Important items in the natural purification of ground water are the character and depth of the strata penetrated.

2. *Adequate protection* by artificial treatment implies that the method of treatment is appropriate to the source of supply; that the works are of sufficient capacity, well constructed, skillfully and carefully operated. The evidence that the protection thus afforded is adequate must be furnished by frequent bacteriological examinations and other appropriate analyses, showing that the purified water is of good and reasonably uniform quality, a recognized principle being that irregularity in quality is an indication of potential danger.

344. Letton. 1917. J. Amer. Water Wks. Assoc. 4, 478-481.

345. Gorman. 1922. Pub. Health Repts. 37, 1458-66; 1573-1580.

346. Connolly and Gorman. 1925. Pub. Health Repts. 40, 1042-1055.

347. Miller and Garthe. 1938. Pub. Health Repts. 53, 300.

3. *Sanitary defect* means faulty condition, whether of location, design, or construction of works, which may regularly or occasionally cause the water supply to be polluted from an extraneous source, or fail to be satisfactorily purified. (Examples were cited in Appendix I.)

An outline of the scope of sanitary survey ordinarily required in the investigation of a water supply to determine whether or not it conforms to these requirements was given in Appendix I.

II. AS TO BACTERIOLOGICAL QUALITY

1. Of all the standard (10 ml.) *portions* examined in accordance with the procedure specified below, not more than 10 per cent shall show the presence of organisms of the *Escherichia coli* group.

2. Occasionally three or more of the five equal (10 ml.) *portions* constituting a single standard *sample* may show the presence of *Escherichia coli*. This shall not be allowable if it occurs in more than—

- (a) Five per cent of the standard samples when twenty (20) or more samples have been examined:
- (b) One standard sample when less than twenty (20) samples have been examined.

NOTE. It is to be understood that in the examination of any water supply the series of samples must conform to *both the above requirements*, 1 and 2. For example, where the total number of samples is less than six, the occurrence of positive tests in three of the five portions of any single sample, although it would be permitted under requirement 2, would constitute a failure to meet requirement 1.

DEFINITION. The *Escherichia coli* group is defined, for the purpose of this test, as in Standard Methods of Water Analysis, American Public Health Association, New York, 1923, and the procedures for demonstration of organisms of this group shall conform to those of the "completed test" as therein specified.

The standard portion of water for this test shall be ten milliliters (10 ml.).

The standard sample for this test shall consist of five (5) standard *portions* of ten milliliters (10 ml.) each.

This was summarized in the *Journal of the American Water Works Association*, volume 10 (1923), p. 885, as follows:

1. *Index Organism.* *Escherichia coli* group, as determined in accordance with Standard Methods of the American Public Health Association, current edition, by inoculation in lactose broth fermentation tube, transplant to endo- or eosin-methylene blue agar plate and inoculate in secondary lactose broth fermentation tube.

2. *Standard Portion of Water.* Ten milliliters.

3. *Standard Sample of Water.* Five standard portions of ten milliliters each.

4. *Limits of Permissible Density of Escherichia coli Group.* Not more than 10 per cent of all the ten milliliter standard portions examined shall show the presence of organisms of the *Escherichia coli* group.

- (a) When the number of standard samples collected is over twenty, not more than 5 per cent of all of the samples shall show three or more positive tests out of the five 10 ml. portions comprised in any single sample.
- (b) When the number of standard samples collected is less than twenty, not more than *one sample* shall show three or more positive tests out of the five 10 ml. portions.

The suggested bacteriological standard was discussed at considerable length. The committee stated that the bacteriological examinations which have come generally to be recognized as of most value in the sanitary examination of water supplies are:

1. The count of total colonies developing from measured portions planted on gelatin plates and incubated for 48 hours at 20°C.

2. A similar count of total colonies developing on agar plates incubated for 24 hours at 37°C. (or in some laboratories incubated 48 hours at 20°C.).

3. The quantitative estimation of organisms of the *Escherichia coli* group by applying specific tests to multiple portions of measured volume.

They omitted the plate counts because the *Escherichia coli* is generally conceded to be the most significant. They stressed, however, the value of the count and advised its use where possible. The two limiting values to the density of *Escherichia coli* were admittedly arbitrary, and represented simply the judgment of the committee.

Some of the widespread benefits of the Federal supervision of water supplies of interstate traffic have been a marked increase in certified supplies and an increased interest in water hygiene (Allen³⁴⁸).

More recent standards have been adopted by the U. S. Public Health Service.^{348a} (These supersede those adopted June 30, 1925.) The bacteriological part is as follows:

1.7. The coliform group of bacteria is defined, for the purpose of this standard, as including all organisms considered in the coli aerogenes group as set forth in the *Standard Methods for Examination of Water and Sewage*, eighth edition (1936), prepared, approved, and published jointly by the American Public Health Association and American Water Works Association, New York City. The procedures* for the demonstration of bacteria of this group shall be specified herein, for:

- (a) The completed test, or
- (b) The confirmed test when the liquid confirmatory medium brilliant green bile lactose broth, two per cent is used, providing the formation of gas in any amount in this medium during 48 hours of incubation at 37°C. is considered to constitute a positive confirmed test, or
- (c) The confirmed test when one of the following liquid confirmatory media are used: Crystal violet lactose broth, fuchsin lactose broth, or formate ricinoleate broth. For the purpose of this test, all are equivalent, but it is recommended that the laboratory worker base his selection of any one of these confirmatory media upon correlation of the confirmed results thus obtained with a series of completed tests, and that he select for use the liquid confirmatory medium yielding results most nearly agreeing with the results of the completed test. The incubation period for the selected liquid confirmatory medium shall be 48 hours at 37°C., and the formation of gas in any amount during this time shall be considered to constitute a positive confirmed test.

1.8. The standard portion of water for the application of the bacteriological test may be either

- (a) Ten milliliters (10 ml.), or
- (b) One hundred milliliters (100 ml.).

1.9. The standard sample for the bacteriological test shall consist of five (5) standard portions of either

- (a) Ten milliliters (10 ml.), or
- (b) One hundred milliliters (100 ml.) each.

In any disinfected supply the sample must be freed of any disinfecting agent within twenty (20) minutes of the time of its collection.†

348. Allen. 1926. Texas State J. Med. 22, 189-194.

348a. Public Health Reports, 58 (1943), 69-111

* This reference shall apply to all details of technique in the bacteriological examination, including selection and preparation of apparatus and media, collection and handling of samples, and the intervals and conditions of storage allowable between collection and examination of the water sample.

† In freeing samples of chlorine or chloramines, the procedure given on page 286 in *Standard Methods for the Examination of Water and Sewage*, 8th Edition (1936), paragraph A-1.—Option 1, or paragraph A-2 shall be followed.

1.10. The certifying authority is the Surgeon General of the U. S. Public Health Service or his duly authorized and designated representatives and the *Reporting Agency* shall be understood to mean the respective state departments of health or their designated representatives.

2. AS TO SOURCE AND PROTECTION

2.1. The water supply shall be.

- (a) Obtained from a source free from pollution, or
- (b) Obtained from a source adequately purified by natural agencies, or
- (c) Adequately protected by artificial treatment.

2.2. The water supply system in all its parts shall be free from sanitary defects and health hazards and shall be maintained at all times in a proper sanitary condition.

3. AS TO BACTERIOLOGICAL QUALITY

3.1. *Sampling*: The bacteriological examination of water considered under this section shall be of samples collected at representative points throughout the distributive system.

The frequency of sampling and the location of sampling points on the distribution system should be such as to determine properly the bacteriological quality of the water supply. The frequency of sampling and the distribution of sampling points shall be regulated by the certifying authority after investigation of the source, method of treatment, and protection of the water concerned.

The minimum number of samples to be collected from the distribution system and examined by the reporting agency or its designated representative each month should be in accordance with the number as determined from the graph presented in Fig. 1† of these standards‡ which is based upon the following population served—minimum number of samples per month relationships:

2,500 and under.....	1
10,000.....	7
25,000.....	25
100,000.....	100
1,000,000.....	300
2,000,000.....	390
5,000,000.....	500

The laboratories in which these examinations are made and the methods used in making them shall be subject to inspection at any time by the designated representative of the certifying authority. Compliance with the specified procedures, or failure to comply therewith, and the results obtained shall be used as a basis for certification, or refusal of certification, by the certifying authority in accordance with the application given below:

3.2. *Application*: Applications 3.21 and 3.22 given below shall govern when ten milliliter (10 ml.) portions are used and Applications 3.23 and 3.24 shall govern when one hundred milliliter (100 ml.) portions are used.

3.21. Of all the standard ten milliliter (10 ml.) portions examined per month in accordance with the specified procedure, not more than ten (10) per cent shall show the presence of organisms of the coliform group.

† For the purpose of uniformity and simplicity in application, the numbers of samples to be examined each month for any given population served shall be determined from the graph (see footnote §) in accordance with the following:

- For populations of 25,000 and under to the nearest 1.
- For populations of 25,001 to 100,000 to the nearest 5.
- For populations of 100,001 to 2,000,000 to the nearest 10.
- For populations of over 2,000,000 to the nearest 25.

§ This figure is not reproduced in this book. From it may be secured the Minimum Number of Samples per Month to be examined in relation to the population served. It may be consulted in Public Health Reports, January 15, 1943.

3.22. Occasionally three (3) or more of the five (5) equal ten milliliter (10 ml.) portions constituting a single standard sample may show the presence of organisms of the coliform group, provided that this shall not be allowable if it occurs in consecutive samples or in more than

- (a) Five (5) per cent of the standard samples when twenty (20) or more samples have been examined per month.
- (b) One (1) standard sample when less than twenty (20) have been examined per month.

Provided further than when three or more of the five equal ten milliliter (10 ml.) portions constituting a single standard sample show the presence of organisms of the the coliform group, daily samples from the same sampling point shall be collected promptly and examined until the results obtained from at least two consecutive samples show the water to be of satisfactory quality.

3.23. Of all the standard one hundred milliliter (100 ml.) portions examined per month in accordance with the specified procedure, not more than sixty (60) per cent shall show the presence of organisms of the coliform group.

3.24. Occasionally all of the five (5) equal one hundred milliliter (100 ml.) portions constituting a single standard sample may show the presence of organisms of the coliform group, provided that this shall not be allowable if it occurs in consecutive samples or in more than

- (a) Twenty (20) per cent of the standard samples when five (5) or more samples have been examined per month.
- (b) One (1) standard sample when less than five (5) samples have been examined per month.

Provided further that when all five of the standard one hundred milliliter (100 ml.) portions constituting a single standard sample show the presence of organisms of the coliform group, daily samples from the same sampling point shall be collected promptly and examined until the results obtained from at least two consecutive samples show the water to be of satisfactory quality.

3.25. The procedure given, using a standard sample composed of five standard portions, provides for an estimation of the most probable number of coliform bacteria present in the sample as set forth in the following tabulation:

Number of portions		Most probable number of coliform bacteria per 100 ml.	
Positive	Negative	When 5-10 ml. portions are examined	When 5-100 ml. portions are examined
0	5	Less than 2.2	Less than 0.22
1	4	2.2	0.22
2	3	5.1	0.51
3	2	9.2	0.92
4	1	16.0	1.60
5	0	More than 16.0	More than 1.60

These newer proposals have caused much discussion among bacteriologists. Suggestions that 100-ml. portions be examined are not new. Hoskins,³⁴⁹ in his discussions of "most probable numbers" of coliform bacteria in water as indicated by results of fermentation tube results, directed attention to the fact that the older method of examining five 10-ml. portions of drinking water samples measures the coli-aerogenes Treasury Department Standard; such content is required to be not in excess of 1.05 per 100 ml. In other words, the measuring stick is too

349. Hoskins. 1934. Pub. Health Repts. 49, 393-405; J. Amer. Water Wks. Assoc. 25 (1933).

coarse for the purpose. The value of this test to the waterworks operator would be greatly enhanced if larger volumes, such as five 100-ml. portions of the sample, were examined which would measure the bacterial content in the range from .22 to 1.6 per 100 ml. By this change in procedure current analytical data would be always available that would indicate when the permissible upper bacterial limit was being approached or slightly exceeded. Such a radical change in technique would introduce modifications of laboratory routine which might be quite expensive. Not all water bacteriologists agree that examination of 100-ml. portions of water would be helpful. Noble³⁵⁰ recommended use of such portions but Norcom³⁵¹ objected. Hoskins³⁵² again, some seven years after his first proposal, made a second statement concerning the proposed changes in standards. One of these concerned examination of larger portions of water than 10 ml. Where coliform density is approximately one per 100 ml. of sample, examination of 10-ml. portions does not permit detection of the coliform group.

Slow Lactose-Fermenting Coliform Bacteria. These organisms, members of the coliform group, ferment lactose with gas formation only after 48 hours. The significance of these organisms in sanitary work has been a problem. *Standard Methods of Water Analysis* stresses formation of gas in 24 hours but places lesser emphasis on its appearance after 48 hours. These bacteria are not of recent origin. They have been recognized to be problems for many years. Berry³⁵³ studied these forms from ground waters including almost every type of dug, driven, or drilled well and a few springs. No seasonal prevalence was noticed. Whether these organisms are devoid of sanitary significance, as was believed in these earlier days, is probably not confirmed by present-day investigations. That they might be good indicators of pollution is indicated by results of investigations by Dulaney and Smith.³⁵⁴ These strains were found in 20 per cent of 400 stools; usually they were present only in small numbers but sometimes made up to 10 to 50 per cent of all colonies. Thirteen per cent of 300 samples of water from various sources contained coliform bacteria which took longer than 48 hours to ferment lactose. These investigators could establish no relationship between slow lactose-fermenting bacteria and the source of the water. While it is known that these bacteria exist in human feces, it is impossible to say that they are of fecal origin, when they are found in water. McCrady³⁵⁵ secured opinions of 30 laboratory workers as to whether they believed it to be desirable in routine work to include in coliform estimates these coliform organisms confirmed from lactose broth presumptive in which less than five per cent or more than 10 per cent gas had been produced after 48 hours' incubation at 37°C. (98.6°F.) from (1) finished or unfinished waters (treated) and (2) natural waters (un-

filtered and untreated). Of 25 replies 15 unqualifiedly favored inclusion in the coliform estimate of coliform organisms confirmed from every lactose broth tube containing gas regardless of amount. Six workers disregarded small gas formers because experience has shown failure to confirm. Only three frankly expressed doubt of sanitary significance of slow lactose fermenters. Following comments are quoted from McCrady³⁵⁵

The question of sanitary significance of the presence in water of coli-like organisms that produce small amounts (five or 10 ml.) of gas in lactose broth, upon incubation at 37°C.(98.6°F.) for 48 hours, has long been the subject of occasional informal discussion by laboratory workers; but in general these slow lactose fermenters have been accepted as genuine members of the coliform group of indicator organisms. *Standard Methods of Water Analysis*, for example, includes such organisms in the coliform group as therein defined. Since it is the usual practice to leave to the control authority the appraisal of the sanitary significance of the presence in a water of any organism of the coliform group, difficulties arising from contradictory evidence furnished, on the one hand, by the laboratory and, on the other hand, by the field survey of the supply are usually (although, unfortunately, not always) readily adjusted.

It is well known that coliform organisms frequently derive from sources unassociated with dangerous pollution, such as multiplication in sediments in mains, on wood, on other material of a vegetable nature, on tap washers, and from virgin soil, that such organisms are frequently atypical in character, and that many of them are slow lactose fermenters. When, therefore, the cause of any excessive coliform density is determined to be other than that of access of pollution to the supply, the coliform report is simply ignored. But is there reasonable justification for dismissing as of no sanitary significance all instances of slow lactose fermentation? One of the principal arguments favoring this course is that slow lactose fermentation is caused by "attenuated" organisms which have become so devitalized that they have lost their sanitary significance. This argument has been so frequently advanced that it deserved particular attention. In the first place, it perhaps will be admitted that the sanitary significance of the presence of coliform organisms in a treated, filtered, or filtered-treated water is ordinarily quite different from that of their presence in a natural water.

Coliform organisms in a natural water serve usually as an indicator of the presence of human, animal, or soil pollution; and, depending upon the further indications furnished by the field survey of the supply, greater or less significance is attached to their presence. When a treated, filtered, or filtered-treated water is examined, however, since it is usually known that the original raw water was polluted, the coliform estimate serves ordinarily, not as an index of pollution that may be more or less dangerous, but rather as a measure of the destruction or elimination by the treatment of associated disease organisms. Here there can be no question of tolerance—if the treatment is satisfactory, practically every disease organism of the raw water will have been eliminated and, by the same token, practically every coliform organism will have been eliminated. There exists no satisfactory evidence that slow lactose fermenters are more resistant to treatment than are typhoid or dysentery organisms; nor may it be contended that a treatment which reduces the gas production of a coliform organism 95 per cent necessarily deprives the typhoid bacillus of its pathogenicity. If, therefore, coliforms of any type persist in a treated water, and if their presence cannot satisfactorily be explained, the conclusion is inescapable that disease organisms may also persist in the water and that the treatment therefore, has not been satisfactory.

Turning now to the question of the significance of slow lactose fermenters in natural waters, it must be admitted that the experienced water bacteriologist is inclined to regard the presence of these organisms with some measure of tolerance, not because they are so attenuated that associated disease organisms may be considered to be deprived of their pathogenicity, but because they are encountered with some frequency in relatively unpolluted soil, in sediments in mains, and on plants. On the other hand, it is well known that the presence of other organisms may reduce or even prevent the production of gas by coliform organisms in the lactose broth tube.

Slow lactose fermenters have been shown by Parr to occur in fresh feces, sometimes in pure cultures. Since he finds that they occur occasionally during periods when the normal intestinal function is impaired, the presence in water of certain slow fermenters may be of more than ordinary sanitary significance. It is evident, therefore, that since the true slow lactose fermenters found in water may have derived from either fresh or stored feces, their presence, even in a natural water, cannot always be considered of no sanitary significance. Since the coliform density of a filtered, treated, or filtered-treated water is a measure of the effectiveness with which the treatment has eliminated disease organisms from the water, it is reasonable to attribute equal sanitary significance to the presence in such water of either typical or atypical coliform organisms, slow fermenters, or rapid fermenters. Slow lactose fermenters are found, although in small proportion, in fresh feces, in greater proportion in stored feces, and occasionally in discharges from cases of gastrointestinal disturbances; the presence of these organisms, even in natural water, therefore, cannot always be dismissed as of negligible sanitary significance. Furthermore, since other organisms contained in the sample may reduce the amount of gas produced in lactose broth by typical coliform organisms, the volume of gas produced cannot be accepted as a sure indication of the type of organism present.

Sanitary bacteriologists have also been troubled with so-called "intermediates" in attempts to differentiate members of the coliform group. These are strains which do not exactly conform to the characteristics of groups of bacteria which have been established. They became quite apparent when attempts were made to differentiate *Escherichia coli* from *Aerobacter aerogenes* by the methyl-red test, Voges-Proskauer reaction, and other reactions. Many strains were isolated which did not conform to the accepted definitions of the two above mentioned bacteria. Kline³⁵⁶ stated that some "intermediates" are mixed cultures. Careful attempts to purify cultures even with single-cell isolations failed to reduce the number of kinds of intermediates. The characteristics of these intermediates were found to be constant. Kline found no evidence for a separate genus such as *Citrobacter*. Mundt and Hitchner³⁵⁷ were able to isolate rapidly fermenting variants from slow lactose fermenters by training in lactose broth. Subculturing under certain conditions raised the percentage of rapid fermenters insufficiently to be of sanitary significance. Ziegler,³⁵⁸ on the other hand, by proper subculturing, was able to transform slow lactose fermenters into rapidly fermenting forms. He believed that such bacteria were as definitely related to fecal contamination as *Escherichia coli*. Ziegler did a little theorizing on the origin of slow lactose fermenters which need not be reviewed here. Experiments by Mundt and Hitchner³⁵⁷ along these lines may be presented briefly. They found that lactose-fermenting habits of some strains could be altered. The progeny of slow lactose-fermenting strains often exhibit marked variations in rate of lactose utilization. Rapidly fermenting variants are readily obtained by training in lactose broth. The purpose of their investigation was to develop strains which would exhibit rapid lactose utilization when in contact with it. Numerous daughter colonies from a slow lactose-fermenting culture, from a rapidly fermenting variant (48 hours) of this culture, and from a variant which failed to ferment lactose in 15 days were transferred to tubes of lactose broth and observed for lactose utilization (acid produc-

358. Ziegler. 1939. Amer. J. Pub. Health 29, 257.

tion). Stock cultures of each of these daughter colonies were maintained on agar slants. From platings made from stock strain of a daughter culture in each series which fermented the sugar within two days or less, a number of subcultures were made and carried through the procedure mentioned above. This procedure was followed through 25 subcultures. The percentage of daughter strains which fermented lactose rapidly (within two days) varied from 12 to 60, with an average of approximately 30. A single exposure of the strain to lactose did not produce 100 per cent of rapidly fermenting daughter strains. Altering composition of the medium by decreasing the organic nitrogen, cultivating in lactose solution with a mineral salt base, using massive inocula, altering the ratio of surface area to volume of test medium, and inoculating with cultures obtained by single-cell isolation did not materially increase or retard the rate of lactose fermentation by these cults. Slow lactose fermenters were grouped by Stuart, Mickle, and Borman³⁵⁹ into several subgroups. They believed that some bacteria now considered to be *Shigella* are really coliform bacteria.

These marginal coliform bacteria were believed by Parr and Friedlander^{359a} to possess as much sanitary significance as the so-called normal forms. An important failing in present technic for coliform bacteria is its inability to determine the presence of these forms.

Density of *Escherichia coli* in Water. Attempts have been frequently made by bacteriologists to learn something about the density of *Escherichia coli* in water. An early result of these attempts was the *coli-index* proposed by Phelps.³⁶⁰ The *Escherichia coli* index is the approximate number of *Escherichia coli* per ml. as determined from qualitative tests made on different quantities of water. For any individual sample, it may be taken as the reciprocal of the smallest volume of water used in the test which gave a positive result. Thus, if a sample gave a negative test with .1 ml. and a positive test with 1 ml. and 10 ml. the *Escherichia coli* index would be 1.0. The *Escherichia coli* index for a single sample is not very accurate. The index becomes more accurate as the square root of the number of tests increases. Phelps pointed out very specifically that the *Escherichia coli* index was of value only when determined for a large number of samples from the same source. It is not used today to any extent and need not be discussed further.

McCrary³⁶¹ proposed a method of calculating the concentration of cells of *Escherichia coli* from a series of dilutions of the water in fermentation tubes. This suggestion was further simplified by Wolman and Weaver.³⁶² Other discussions of such averages were prepared by Streeter³⁶³ and Reed.³⁶⁴ The former suggested expression of *Escherichia coli* densities in terms of "most probable numbers."

364. Reed. 1925. Pub. Health Repts. 40, 693-721.

A method of arriving at "most probable numbers" proposed by Hoskins³⁶⁵ is generally used today for indicating the concentration of coliform bacteria in water. It is derived from results of the dilution method for quantitative bacteriological analysis of samples. Based on a probability equation derived by Reed, Hoskins proposed his method for computing the "most probable number" per ml. to two significant figures of coliform bacteria in any sample, regardless of the number of portions examined, number of dilutions, amounts of dilutions, whether or not in geometric series. Hoskins and Butterfield³⁶⁶ criticized the Phelps index but admitted that an absolutely satisfactory method is not yet available for determining promptly and definitely whether water is free from bacteria causing disease. The next best procedure is to determine the density of the indicator organisms. It leaves much to be desired, however. Another attempt to solve this problem was made by Buchanan and Wollaston.³⁶⁷ It was recommended that the number of fertile tubes be employed rather than the most probable numbers of bacteria per 100 ml. Georgia³⁶⁸ proposed a system of most-probable-range (M.P.R.) as preferable to the most-probable-number for coliform concentration. He stated that low concentrations are better detected by increase in the number of 10-ml. tubes than by adding 100-ml. tubes. Other proposals were made by Thomas³⁶⁹ and Swaroop.³⁷⁰

One way to avoid using the indirect methods described above is to develop a solid plating medium for direct estimation of coliform bacteria. Several good ones have been proposed but have never been adequately investigated. They merit more study.

Bacteriological Standards for Potable Water. The ultimate purpose of analyzing water is to determine if it is safe to drink. To determine this the results of an analysis must be compared with "standards" which have been arrived at in previous study. The best known standard in the United States was that of the Treasury Department of not over one coliform cell per 100 ml. of water. Some sanitarians consider this to be lenient. Harting³⁷¹ has suggested that this standard might not be a sufficient safeguard against all water-borne disease. It has been suggested that mild and semi-mild intestinal disturbances, which become epidemic could be water-borne, even though the water in question satisfied Treasury Standards. While epidemiological data do not support such an opinion, they argue that drinking water should be above mild suspicion which they believe is possible only when water is bacteria-free.

The Metropolitan Water Board of London, England,³⁷² is operating under a classification of water which has been used for many years. These

standards are based upon the coliform bacteria content of a water supply and seem to have been workable over many years. Taking the coliform content of sewage as about 100,000 per ml., they have grouped water into nine classes depending on the concentration of coliform bacteria. The first class permits none in 100 ml. The other classes contain more and more coliform bacteria until the ninth class is undiluted sewage.

The Metropolitan Water Board recognizes but one standard for water and that is the highest quality indicated by them as first-class. The Ministry of Health of Great Britain³⁷³ also has standards but believes they should not be interpreted too rigidly but that serious discrepancies should be investigated promptly. Their standards are based on the presumptive coliform count in 100 ml. piped supplies: Class 1, highly satisfactory, less than 1; Class 2, satisfactory, 1-2; Class 3, suspicious, 3-10; Class 4, unsatisfactory, greater than 10.

Some difficulties of an arbitrary standard applied indiscriminately to all samples, regardless of source and intervals between sampling, may give a false opinion concerning plant operation according to Borman *et al.*³⁷⁴

Microorganisms in Sterilized Water. These are microorganisms which are too chlorine-resistant to be destroyed by doses of chlorine usually used in water purification. Not much is known about resistance of ordinary species of bacteria to chlorine. The minimal "chlorine death points" required to kill in 15 to 30 seconds were determined for 503 strains of 48 bacterial species by Tonney *et al.*³⁷⁵ Intestinal and respiratory vegetative pathogens were killed by .15 to .25 p.p.m. in 15 to 30 seconds; *Escherichia coli* was somewhat more resistant. Spore-bearers were 10 to 1,100 times more resistant than vegetative cells. Chlorine death points of spores ranged from 2.5 p.p.m. for *Clostridium welchii* to 280 p.p.m. for *Bacillus vulgatus*. *Bacillus subtilis* at 160 p.p.m. was considered best adapted and safest as an index organism of the spore-bearer group. The primary purpose of chlorination is to safeguard against a relatively few intestinal and respiratory vegetative pathogens. Regular and consistent destruction of *Escherichia coli* appears to be a more suitable practical criterion of effective chlorine disinfection than the total bacterial count or *Bacillus subtilis*. Other chlorine resistant nonsporeforming bacteria were studied by Charlton.³⁷⁶ The chlorine species encountered in a public water supply were pigmented, Gram-negative rods. Most of them were assigned to *Pseudomonas* and *Flavobacterium*. They were more resistant to chlorine than intestinal rods as *Escherichia coli*. According to Plucker and Gautsch,³⁷⁷ from .05 to .2 p.p.m. of free chlorine, acting for one hour, is more effective against *Escherichia coli* than either sodium hypochlorite or chloramines, at equivalent concentration. Results of similar experiments by Heathman and Pierce³⁷⁸ indicate that the power of chlorine-treated water varies con-

siderably within certain limits, but that the killing time is, in a majority of instances, much greater at low than at room temperatures. While there is an appreciable variation in the resistance of freshly isolated strains of *Eberthella typhosa* to the disinfectant action of chlorine and chloramine, as a rule recently isolated strains of *Eberthella typhosa* were more resistant than old laboratory strains of this organism. In many instances freshly isolated strains of *Eberthella typhosa* were more resistant to the disinfectants than members of the coliform group. It appears there is a possibility of *Eberthella typhosa* living in chlorine or chloramine-treated waters as long as or longer at times than coliform. That chlorine sterilization of water is influenced by many factors was also shown by Rudolph and Levine.³⁷⁹ This probably explains why troublesome bacteria survive treatment in some waters. Some lactose fermenters are in this group. They form gas in the presumptive test but do not confirm.

It is believed by some that some strains of *Escherichia coli* may be more resistant to chlorine than others and that such strains may thus appear in chlorinated water. Borman, Robinton, and Stuart³⁷⁴ found no such forms nor evidence that coliform bacteria are more resistant.

Maintenance of chlorine residuals between .2 and .4 p.p.m. has generally been considered to be satisfactory for insuring coliform bacteria-free water. Levine, Carpenter, and Coblentz³⁸⁰ however, stated that this was not a dependable criterion of water sterilization since nonsporeforming coliform bacteria may be isolated from waters having high chlorine residuals. Since the presence of coliform bacteria in water is the index of potability of a water supply, it is important that they be eliminated. Freiberg³⁸¹ observed coliform bacteria in water with as much residual chlorine as .5 to .8 p.p.m. Coblentz and Levine³⁸² described an organism meeting the definition of the coliform group as defined in *Standard Methods for the Examination of Water and Sewage* which resisted exposure to .6 p.p.m. chlorine plus .6 p.p.m. ammonium sulfate for one and one-half hours at 0°C.(32°F.) with residual chlorine of .45 p.p.m.

STERILIZATION OF WATER

Water is sterilized in the food industry to make it safe and to destroy microorganisms which may deteriorate foods. It may be treated in large quantities to make it safe for use, i.e., to destroy disease-producing bacteria. Examples of such troublesome microorganisms are mentioned early in this chapter. The method used depends on various factors such as cost, the amount of water to be treated, and the type of microorganisms to be destroyed.

Filtration. Various types of filters have been used varying from those made of sand to those made of special materials. The former are used largely for treatment of large quantities of water. It is not an infallible method, for some other method is required to destroy microorganisms

379. Rudolph and Levine. 1938. *J. Bact.* 35, 3.

which may pass through the filters. Filters of sand remove most of the microorganisms and much of the suspended matter. Other fillers have also been adopted in filters, such as activated carbon, diatomaceous earth, and asbestos. Activated carbon filters remove few bacteria but do remove flavors, odors, and colors. Asbestos and diatomaceous earth filters are bacteriologically satisfactory but require periodic washing or replacement.

The Seitz EK filter with surface of 350 square centimeters was tested by Boars and Lecluse-Asselbergs.³⁸³ Results were found to depend on numerical density of organisms and on amount of suspended matter. The filter soon becomes permeable to bacteria and is clogged by suspended matter with reduction in filtration rate. They concluded that this filter was limited to sterilization of clear water containing only a few bacteria and even then it must be frequently changed or sterilized each time before use. It was of little value in sterilizing water with much suspended matter or contaminated muddy water.

Filtration has been used for purifying small quantities of water in homes. Many have been found to be unreliable. Bruns³⁸⁴ observed that those which were filled with sand of a grain size of one mm. diameter retain only about 10 to 20 per cent of the bacteria. With a grain size of .5 mm. about 50 per cent of bacteria were retained, but "loss of head" was greatly increased.

Iodine. Iodine has been much recommended for emergency sterilization of drinking water, especially on a small scale. Pond and Willard³⁸⁵ undertook a series of tests in which water, inoculated with one drop of a prepared *Escherichia coli* suspension, was subjected to the action of an iodine tincture of definite strength. The samples of water were then placed in a water bath at 17°C. (62.6°F.) for a contact period of 15 minutes. The bactericidal action was terminated by adding an excess of sodium thiosulphate and the water samples then examined. In 10 experiments a reduction in bacterial content of 99.999 per cent was obtained in six cases, 99.99 per cent in three cases, and 99.9 per cent in one case. The last case was that of a river water heavily polluted with organic matter. In a second series of 25 experiments all cases showed a reduction of 99.999 per cent.

A period of 15 minutes' contact was selected as being the maximum time to wait before drinking, although earlier investigators have suggested a 30 minutes' contact period. Conteras³⁸⁶ believed iodine was a better purifying agent for water than any other known substance. It was said to equal chlorine and to be more easily applied.

Metals. That metals have a detrimental action on bacteria has been known for a long time. Harmful effects were noticed by Naegeli, who proposed the terms oligodynamy and oligodynamic action. Since these early days, many others have reported results of investigations and various patents have been issued. It will be impossible to review all of the literature here.

In recent years ionic silver has been much studied, and a method known as the Katadyn Process has been used for getting the silver into the ionic state. The Electro-Katadyn-Sterilizer consists of two silver electrodes from which the silver is dissolved. The silver ions are discharged into the water from silver electrodes by a weak current. The amount of silver entering the solution can be regulated by the strength of current. It has been used for sterilization of water and food. The literature has become quite voluminous. Ruge³⁸⁷ and Walton and Ayyar³⁸⁸ observed good results when using the Katadyn method. Krause³⁸⁹ observed that pure metals had oligodynamic action which differed from their germicidal activities. Colloidal silver was effective against bacteria, and water containing it remained germicidal. Degwitz,³⁹⁰ found the method so effective that 100,000 coliform bacteria were killed in 10 minutes. Similar results were reported by Samaan.³⁹¹ However, he said that colloidal silver was less effective than ionic. As is the case with most disinfecting reactions, Gibbard³⁹² found temperature to be of considerable importance. Low temperatures retarded it as did presence of organic matter. While Gibbard observed germicidal properties in water so treated, he did not recommend the method for practical use at that time. Interfering factors were also noticed by Brandes,³⁹³ who said that .05 p.p.m. would sterilize water and that the contact period depended on turbidity, composition, and hydrogen-ion concentration.

According to Metalnikoff³⁹⁴ the silver must be the anode to exert germicidal action. Such bacteria as *Escherichia coli*, *Microspira cholerae*, *Salmonella paratyphi*, *Eberthella typhosa*, and *Staphylococcus aureus* were all killed in a few minutes and often in a few seconds. Boiling did not destroy the bactericidal property; it remained in the water for over three months. The concentration of silver in the water depended on the length of exposure to the electric current. A concentration of silver of one part in 5,000,000 killed *Escherichia coli* and staphylococci in three hours. Myers and Mauer³⁹⁵ reported similar results; .10 to .15 p.p.m. of silver was sufficient to destroy 250,000 *Escherichia coli* cells per ml. of river water, or neutral distilled water, in 2.5 hours. *Staphylococcus aureus* was only a little more resistant.

Whether silver in water and foodstuffs would be harmful has never been adequately studied. Gibbard³⁹⁶ pointed out that the silver ion was one of the most active ions. Since water containing colloidal silver has been recommended in many different kinds of foods Gibbard believed that the matter should be studied by health officials.

Ozone. The general bactericidal aspects of ozone have been reviewed in Chapter 1. It is not widely used even for sterilization of such a sub-

stance as water. In addition to its sterilizing ability, it reduces color, odor, and flavor and leaves nothing of a deleterious nature in the water. Historical information as well as its effect on various bacteria has been presented by Lipkowski³⁹⁷ and Rich.³⁹⁸ Its bactericidal action has been well established and it has wide application in France and Belgium.

Ultraviolet Light. Germicidal properties and practical use of this form of energy have been discussed in several places in this book. It now has a voluminous literature. There seems to be little doubt about the efficiency of the method if the rays can penetrate to the bacteria. It is a method which may be adapted to sterilization of water used in special industries, such as brewing, distilling, and dairying where it may be necessary.

One difficulty which should be considered is the low penetrating power through liquids containing various substances in suspension or solution. Courmont and Nogier,³⁹⁹ who had previously shown that immersion of a mercury vapor quartz lamp in clear water destroyed ordinary bacteria and coliform bacteria within a distance of 30 centimeters in about a minute, showed here that colloidal substances, such as liquids with organic matter, were not easily penetrated. To treat some materials very thin layers must be used. This was found to be necessary by Maurain and Warcollier.⁴⁰⁰ Sterilization of many substances is therefore limited to the surface. Turbidity and color were found by Oker-Blom⁴⁰¹ to retard germicidal properties of ultraviolet light. His observations were made with various pure cultures of bacteria. He added more data but they did not change the trend of opinion. Under practical conditions in large water plants turbidity would probably be a great problem. In Dallyn and Parkinson's⁴⁰² experiments, turbidities of five to 20 p.p.m. permitted bacterial removal of 97 per cent; 20 to 50 p.p.m. permitted a removal of 94 to 97 per cent. They believed that ultraviolet sterilization was a feasible method even though there were certain complicating factors.

Henri, Helbronner, and von Recklinghausen⁴⁰³ devised an apparatus in which large quantities of water could be treated. Water inoculated with coliform bacteria, when pumped through it at the rate of 36 cubic meters per hour, was completely sterilized. Suspensions of pathogenic bacteria were sterilized in a short time. Similar results were secured by Grant⁴⁰⁴ in the laboratory of the Sorbonne in Paris. He believed that he had shown the possibility of sterilizing water on a large scale. Fischer⁴⁰⁵ found this treatment of water satisfactory for breweries. Favorable results were also reported by Spencer,⁴⁰⁶ Smith,⁴⁰⁷ Blocher,⁴⁰⁸ and Springer.⁴⁰⁹

The last mentioned studied especially the cost of sterilization of water with ultraviolet light. That water to be sterilized in this manner had to be clarified should not be charged against this method. It should be done regardless.

Most of the work on germicidal action of ultraviolet light has been done with quartz lamps. Other sources of this form of energy are also possible. Davies ⁴¹⁰ reported that sufficient ultraviolet rays are emitted from iron arcs to yield appreciable results. These rays, however, did not seem to have great penetrating powers.

This method of sterilization has certain benefits over other methods. It does not change the water. Especially important is the fact that no changes in taste are involved, which is not the case with some other practical methods.

Copper Salts. These were once considered to be active germicides. While they were mainly studied for disinfecting large bodies of water, such as reservoirs, they were also used for smaller amounts. Moore and Kellerman ⁴¹¹ and Kellerman and Beckwith ⁴¹² found copper sulfate satisfactory for destruction of bacteria in water. Considerable variation in susceptibility was observed among the bacteria which were used. The time factor was quite important. Stone and Monahan ⁴¹³ found copper sulfate in a concentration of one part in 4,000,000 of water to possess appreciable effect on bacteria. Vincent ⁴¹⁴ observed marked germicidal action of copper sulfate on *Bacillus perfringens*. Stewart ⁴¹⁵ concluded from results of experiments that water could be purified by standing in copper vessels for three hours. This same possibility was investigated by Kraemer ⁴¹⁶ and Pilod and Codvelle ⁴¹⁷; the former suggested use of copper strips which were to be allowed to stand in the water overnight. This method of sterilizing water never had wide application because other more satisfactory methods were developed and because copper was looked upon with considerable suspicion.

BACTERIOPHAGE IN WATER

For a long time it has been known that the water in certain rivers in India has been germicidal. When d'Herelle announced the discovery of bacteriophage, he gave an explanation for these observations. Russell ⁴¹⁸ observed the action of natural waters on bacteria, which might have been due to bacteriophage. When *Eberthella typhosa* and coliform bacteria were inoculated into boiled waters (surface, deep well, and spring) growth generally occurred. This was more marked with the latter than with the former, and was most pronounced where the seeding was light. When the same cultures were exposed to the action of water filtered through a Chamberland or Berkefeld filter or to etherized water from which the anaesthetic

had been removed by aspiration, growth not only did not take place, but the numerical content was greatly reduced so that the cultures became sterile within 24 hours. Tests showed that if filtered water was heated to 60°C. (140°F.) for 10 minutes it lost its toxic power. The origin of the toxic substances was ascribed to the development of water bacteria. After incubation for 33 days, this water was again filtered and found toxic for typhoid and coliform bacteria, and upon heating, it again lost its toxicity. The demonstration of the existence of bacteriophage in water has given new interest in this subject. Arnold⁴¹⁹ found bacteriophage present in Chicago River water in varying amounts. The concentration was in direct proportion to the amount of sewage. Arnold believed that such bacteriophage would influence the bacterial content of water.

Arloing and Sempe⁴²⁰ described results which they secured with water of the Rhone and Saone rivers, using various species of organisms, *Escherichia coli*, *Salmonella paratyphi*, *Salmonella schottmülleri*, *Eberthella typhosa*, and *Eberthella dysenteriae*. The water of the Rhone and Saone rivers possessed inhibitory powers for the above bacteria. *Escherichia coli* seemed to be more sensitive than the other organisms. In general, the water of the Saone possessed greater inhibitory power than the water of the Rhone. Water from the latter, however, was more active against *Eberthella typhosa*. Arloing and Chavanne⁴²¹ extended these observations to other rivers. The results in each case show the presence of a lytic principle. Arloing, Sempe, and Chavanne⁴²² explained the antagonistic action of the waters, examination of which has just been reported, as due to a polyvalent bacteriophage. They were led to this explanation rather than to the presence of salt, etc., because dilution did not prevent lysis and increase of virulence occurred under conditions similar to those in which d'Herelle's principle was exalted.

The reaction of water was related to longevity of bacteriophage by Marginesu.⁴²³ In alkaline water the phage against various pathogenic bacteria could always be detected. When the pH was 5.2, phages for *Escherichia coli* and *Staphylococcus* could be found but not that for *Eberthella typhosa* or *Shigella dysenteriae*. In water with a pH of 3.5 no bacteriophages were found. These observations were confirmed by observations in the laboratory. Chemical impurities from industrial plants were reported by Segre⁴²⁴ to have little effect. He found various bacteriophages present.

In general those who have found bacteriophage in water have been able to relate it to evident fecal pollution. This was the experience of De Assuncao and Rodovalho,⁴²⁵ Gildemeister and Watanare,⁴²⁶ and Schloss-

mann.⁴²⁷ Bacteriophage probably plays little role in purification of water (Gildemeister,⁴²⁸ Stewart and Ghosal,⁴²⁹ and Flu⁴³⁰).

Presence of bacteriophage in water was given sanitary significance by Pasricha and de Monte,⁴³¹ based on the assumption that presence of bacteriophage active against intestinal pathogens from the human intestines indicates contamination by individuals who harbor such bacteria. This assumption was supported by results of examination of 516 samples of water.

Pasricha and de Monte's (1941) Method Detecting the Presence of Bacteriophage in Water. Twenty-five ml. samples of water are collected in sterile containers. Each sample is added to 50 ml. of nutrient broth or peptone water to which are added one ml. each of young cultures of smooth strains of *Vibrio cholerae*, *Eberthella typhosa*, *Shigella dysenteriae*, Shiga and Flexner types. The mixtures are incubated for 48 hours, .1 ml. M. sodium hydroxide being added if necessary to maintain an alkaline reaction, and filtered through a diatomaceous earth filter. The filtrates are tested for bacteriophages by the drop method.

Viruses in Drinking Water. Viruses are not ordinarily spread by water. Information on this question, however, is not definite. If there are exceptions, the best known are those causing poliomyelitis and swimming pool conjunctivitis. Kling⁴³² reported finding the former in water. In view of this fact Levaditi, Kling, and Lépine⁴³³ were led to investigate the effect of chlorination on the virus in water. They reported that four p.p.m., of chlorine destroyed the virus in cloudy tap water, while .4 p.p.m. was equally effective with clarified portions. As Kempf and Soule⁴³⁴ stated, the above authors did not control pH and temperature nor did they determine the minimum effective chlorine concentration nor the shortest effective contact period. Kempf and Soule observed no virucidal action of chlorine in a concentration of .5 p.p.m. in one and one-half hours, a concentration in excess of that usually used in practice.

Bacteria in Bottled Waters. Bottled waters are used because of their special mineral content and because some people lose faith in their local water supply. The sanitary condition of bottled waters depends on the sanitary quality of water before bottling and also on methods employed during bottling. Both of these factors are carefully watched by the larger bottlers of mineral waters for advertising purposes, if for no other reason. Obst⁴³⁵ conducted an examination of bottled waters from 110 American springs and 57 sources in foreign countries. The usual Standard Methods were used. Bacteriological analyses indicated an uncalled-for condition in these waters, since people are led to believe that bottled waters are clean and harmless. Some brands of water were found to contain *Escherichia*

coli in such numbers that the water would not conform to any standard which could be imagined for public water supplies. Obst considered an extreme standard to be essential for such types of water. No water should be sold which gives any indication whatever of contamination at the source. Sanitary inspections at the source should be made to insure the proper care in the bottling establishments.

A few data on this subject were also published by Bauce and Caillon.⁴³⁶ The hydrogen-ion concentration of 21 bottled mineral waters varied between 6.0 and 7.6. The number of bacteria per ml. varied from 0 to 10 in 10 samples, from 10 to 100 in five samples, from 100 to 1,000 in three samples, and 400,000 in one. Only one sample contained *Escherichia coli*. This same variation in bacterial content was observed by Kliewe and Lang.⁴³⁷ Some harbored as many as 55,000 per liter. The State Departments of Health of New York⁴³⁸ and Florida⁴³⁹ reported that some bottled waters were bottled under quite unsanitary conditions. While the water as it came from the ground was satisfactory, examination after bottling revealed the presence of *Escherichia coli* in 10-ml. quantities. It is quite probable that what has been said above about bottled waters might not be true today.

Carbonated Waters. In carbonated water the bacteria must survive almost the same conditions as in the carbonated beverages. The viability of certain members of the colon-typhoid group in carbonated waters was studied by Koser and Skinner.⁴⁴⁰ Carbonation caused sharp diminution in the numbers of *Escherichia coli*, *Eberthella typhosa*, and *Salmonella paratyphi*. At room temperature the destruction was more marked. Spore-forming bacteria were found to be quite resistant.

The effect of carbon dioxide under pressure on water bacteria was also tried by Colin.⁴⁴¹ *Escherichia coli* resisted a pressure of 25 kg. for more than five days. *Shigella dysenteriae* was destroyed in less than 15 hours at 15 kg., and in less than six hours at 20 kg. The cholera organism was destroyed in less than 10 hours at 10 atmospheres. Other organisms gave similar data. A pressure of 25 kg. on a sample of polluted Seine River water killed all of the bacteria except *Bacillus subtilis* in a few hours. Guillerd and Lieffrig⁴⁴² found that water artificially saturated with carbon dioxide showed practically no bactericidal action against *Escherichia coli* or *Eberthella typhosus*. Practically no reduction in numbers was evident after exposure of 40 minutes in their experiments.

BACTERIOLOGY OF ICE

In former times much natural ice was harvested and stored until used in the summer. When natural ice was widely used, questions were always

raised with respect to its sanitary quality, for much of it was harvested from bodies of water of questionable sanitary condition.

Artificial ice is produced mostly by the can method. These are usually about the size of an ordinary cake, and, before freezing, are filled with distilled water; if ordinary water with a high mineral content is used, the cake of ice, after it has been frozen, will have a white core through the center. This is formed from the dissolved and suspended matter and will also contain the bacteria which were present in the original water.

The State of Connecticut⁴⁴³ has inspected artificial ice plants for the purpose of enforcing sanitary code regulations adopted by the public-health council. While they admitted that the possibility of ice becoming contaminated and remaining so for a long period was slight, it was nevertheless desirable that ice should be obtained or made from safe water and under clean conditions.

Ice does not furnish the essentials of a good medium and consequently there is no multiplication of bacteria. The question resolves itself into determining how many bacteria may survive in such an environment. The following factors contribute to the inhibitory action on bacteria: temperature, lack of oxygen, and absence of moisture. Longevity of bacteria in ice has received some attention from bacteriologists and sanitarians. Frankland⁴⁴⁴ reported data which were secured by Prudden. Cultures of *Serratia marcescens* (*Bacillus prodigiosus*), *Bacillus proteus vulgaris*, *Staphylococcus pyogenes aureus*, a fluorescent bacillus, and *Eberthella typhosa* were put into samples of water and exposed to temperatures of $-10^{\circ}\text{C}.$ ($14^{\circ}\text{F}.$) to $-1.1^{\circ}\text{C}.$ ($30^{\circ}\text{F}.$) for 103 days. *Bacillus prodigiosus* decreased from 6,300 in four days to 3,000; in 37 days the number went to 22, and after 51 days, all of the cells had died. *Bacillus proteus vulgaris* disappeared in 51 days. At the end of 11 days there were 1,000,000 cells of *Eberthella typhosa* and 7,000 after 103 days. Alternate freezing and thawing were very detrimental to bacteria. Experiments with anthrax vegetative and spore cells indicated that the spores resisted for some time, while the vegetative cells were rather quickly destroyed. The cholera vibrio was reported to have been destroyed in from six to 10 days.

Chemical and bacteriological studies by Clark⁴⁴⁵ with ice gathered in different localities in Massachusetts showed that ice contains less of both suspended and dissolved matter than the water from which it is formed. The same is true for bacteria, particularly if there is a considerable depth of water under the ice, and the water is quiet during the process of ice formation. When, in order to thicken ice, that already formed on a pond or river is flooded and the entire volume of water over the ice is frozen, bacteria will undoubtedly be retained in this ice. It was stated by Clark then when *Echerichia coli* and *Eberthella typhosa* were frozen in the ice they retained their vitality for a number of weeks, the exact limit not having been determined. It was also stated that if there was a considerable depth of water in portions of a somewhat polluted pond or river, and ice

was formed in these portions in comparatively quiet water with but little matter in suspension, such ice would probably be entirely satisfactory for domestic use, although considerable drainage may enter the body of water upon which it forms. On the other hand, ice formed in shallow portions of such ponds or rivers, even during still weather, or in any portion if there is a considerable movement of the water by currents or wind while it is forming, may be rendered by these conditions entirely unfit for domestic use.

Ice and Typhoid Fever. The general consensus of opinion among sanitarians is that ice is not an important epidemiological factor in the spread of typhoid fever. Reudiger⁴⁴⁶ secured data with *Escherichia coli* and *Eberthella typhosa*. From this it is apparent that 99.9 per cent of the *Eberthella typhosa* die during the first eight days. Park⁴⁴⁷ also reported experiments in which 20 cultures of *Eberthella typhosa*, after having been grown for 28 hours in agar, were placed in a room, the temperature of which was rather constant at 23°F. At the end of a week, only 14 per cent of the bacteria were alive, and at the end of 22 weeks, all of the cultures were dead. Watery suspensions of different bacteria were placed in small tubes and dropped into liquid air, exposures being from three minutes to two hours and 10 minutes. As a result of this pressure, the virulence of the organisms was only slightly decreased. Jordan, Russell, and Zeit⁴⁴⁸ found that in filtered water *Eberthella typhosa* died rapidly. Two organisms were found after the first day, and none later. Hilliard *et al.*⁴⁴⁹ reported that 99 per cent of *Escherichia coli* were destroyed by freezing in tap water for three hours. *B. subtilis* showed a less uniform reaction. No apparent difference was noticed by these investigators between alternate freezing and continued freezing. Hutchins and Wheeler⁴⁵⁰ reported an ice-borne epidemic but Hill⁴⁵¹ believed the evidence to be inconclusive. The characteristics of the epidemic did not agree with those which Hill thought an ice-borne epidemic should have. Jordan⁴⁵² and Bartow⁴⁵³ belittled ice as a cause of illness. Conway,⁴⁵⁴ after a careful investigation, was led to conclude that an outbreak of typhoid fever at Elmira, N. Y., was due to the consumption of a superficial layer of natural ice harvested from a heavily polluted river, even though this ice was stored for between five and six months. Conway believed that a real danger existed in the use of polluted ice directly in drinks. Bacteriological analysis of the ice indicated pollution. There were 140,000 bacteria per ml. at 20°C. (68°F.), and 1,300 per ml. at 37°C. (98.6°F.). *Escherichia coli* was present in one-tenth ml. quantities.

Whether *Eberthella typhosa* might survive in ice would depend on various factors, such as number of cells present, age of the ice, and perhaps presence of organic matter. Results of experiments on longevity of *Eberthella typhosa* in ice are contradictory. Lascu⁴⁵⁵ found that they would survive for months, while Thomas⁴⁵⁶ took the opposite position. As is the case with foods in general, ice must be handled in a cleanly manner. Schulze and Karff⁴⁵⁷ found evidence of pollution in ice which had been crushed and placed in unsanitary containers.

Methods for the Bacterial Examination of Ice. After ice has been sampled and the sample is melted, the methods of analysis, chemical and bacterial, are no different from those used in water analysis. The sampling of the ice for the bacteriological analysis does, however, require some special attention. Care must be exercised to secure a sample which is not contaminated. This may be accomplished in different ways. The block of ice should be carefully cleaned and washed with distilled water. Then, it should be copiously rinsed with sterile distilled water. After this it should be split, if it is a large block, and small pieces chipped off and transferred to sterile containers by means of sterile instruments. If this is carefully carried out, no contamination will result. The block may also be bored out with a sterile auger and the shavings collected in a sterile bottle. Greenfield⁴⁵⁸ has described an instrument for sampling ice. It is constructed after the cheese sampler.

Longevity of Pathogenic Bacteria in Natural Waters. This is an important subject in sanitary work. The relative longevity of pathogenic bacteria and the various indicators of pollution must be known. In view of the various conditions under which experiments have been carried out, some confusion among results exists. This situation is not difficult to explain. This subject came to the fore in the so-called Illinois River case,⁴⁵⁹ in which the City of St. Louis and the State of Missouri sued in the courts to prevent the City of Chicago from using the Illinois River for disposing of its sewage. The plaintiffs argued that pathogenic bacteria, such as *Eberthella typhosa*, could live in the Illinois River and eventually enter the St. Louis water supply. Several investigations were carried out to secure information on this possibility.

Jordan, Russell, and Zeit⁴⁶⁰ studied this question in both pure and polluted waters. They suspended bacteria in collodion sacs in both pure and polluted waters. In pure Lake Michigan water, the bacilli did not die out until after a week, but three days seemed to be the limit for the polluted Chicago Drainage Canal water. Russell and Fuller⁴⁶¹ confirmed these results, using pure Lake Michigan water and sewage as the menstrua. In this experiment, the bacilli lived for about 10 days in Lake Michigan water and three days in sewage. Houston⁴⁶² has studied this question in England. He points out that one-ml. samples were used by the American workers in most of the cases, and from these small samples conclusions were drawn with regard to the longevity of *Eberthella typhosa*. When no

462. Houston. Various reports from Met. Water Bd.

organisms were found in one-ml. samples, it was stated that the organism had died out. Probably American bacteriologists have been too much accustomed to use small amounts of water in analytical work. Houston carried on experiments, using Thames, Lee, and New river waters, using 100-ml. quantities of the water as the maximum amounts examined. For 100-ml. quantities in 18 experiments, it required nine weeks for the total disappearance of *Eberthella typhosa*. Ninety-nine per cent of them disappeared in one week under laboratory conditions of the experiment. The above data of both American and English bacteriologists indicate the value of storage. The rate of death of *Eberthella typhosa* and *Escherichia coli* in pure natural water has been reported by Rahn and Hinds⁴⁶³ to follow the monomolecular law. Under these conditions, the rate increased with the temperature. Oxygen was found to be harmful to *Escherichia coli* but beneficial to *Eberthella typhosa*.

In the laboratories of the Metropolitan Water Board of London (Whipple⁴⁶⁴), it was found that 99 per cent of the original number of *Eberthella typhosa* in river water died in one week, and of the remainder some lived for five to eight weeks. Uncultivated strains seemed to die more quickly; when the effect of temperature was studied, the following storage periods were necessary for the different temperatures given to reduce *Eberthella typhosa* organisms from 100,000 to three per ml.: five weeks at 32°C. (89.6°F.); four at 40°C. (104°F.); three at 50°C. (122°F.), and two at 64.4°C. (148°F.). Houston believed that storage for four weeks provided a reasonable margin of safety. Houston in the Second Research Report reported the results of attempts to isolate *Eberthella typhosa* from water. He examined, all told, 29,400 ml. from 156 samples of raw river water for the presence of this organism. This involved 7,329 colonies; all of the results were negative. Houston believed that *Eberthella typhosa* was not present in raw water in large numbers. These results were confirmed by investigations which were reported on the Fifth Research Report. In the Sixth Research Report Houston stated that "uncultivated" *Eberthella typhosa* tended to die in river water during storage more than the "cultivated" strains. He claimed that these data enhanced the importance of his statements about the value of storage. Wibaut and Moeus⁴⁶⁵ attempted to find out why *Eberthella typhosa* disappeared from water. Specimens of water were inoculated and stored under different conditions. The organism disappeared from tap water, rain water, and swimming pool water in seven to 10 days. Their disappearance corresponded with a marked increase of a bacteria-eating protozoon. Less clear-cut results were secured when the cells were put into ground water. In one experiment, the cells of *Eberthella typhosa* remained for four weeks in spite of the presence of the protozoon. These authors concluded that other factors, besides the protozoon, also helped to explain the disappearance of the bacteria. For all practical purposes, Houston believed that a storage period of four

weeks was adequate to render a water safe as far as *Eberthella typhosa* is concerned.

Houston also showed that temperature was a very important factor in the question of the longevity of *Eberthella typhosa* in water. He found that the lower the temperature, the longer the organism lived in water. The water in these experiments was artificially inoculated and stored at the several temperatures which were used. Greer⁵⁴ confirmed Houston's conclusions. He reported that *Eberthella typhosa* lived longer in colder water than in warm water. Various factors, such as hydrogen-ion concentration, sunlight, and temperature, among others, were said to influence the death of bacteria in water.

Presence of organic matter is important in longevity experiments. Vacek⁴⁶⁶ found it to be important along with other factors. He artificially contaminated water from several sources with *Eberthella typhosa*, observing survival times varying from seven days with distilled water to 14 days with filtered water at 20°C. (68°F.). Water was believed to behave as a nutrient medium even though it contains only a little nitrogenous matter. Varying survival periods have been reported for this organism in water by Violle,⁴⁶⁷ Ballantyne,⁴⁶⁸ Warner,⁴⁶⁹ Mouzet⁴⁷⁰ and Heukelekian and Schuloff.⁴⁷¹ The latter observed disappearance of *Eberthella typhosa* to be rapid in sewage and polluted water. Several days' storage resulted in 99 per cent reduction with heavy initial infection. For short periods, they observed increases but these were overcome by rapid death rate later.

Schepilewsky⁴⁷² concluded that, as a rule, natural waters are able to free themselves quickly of bacterial contamination. The purification of the water from bacteria is largely dependent upon the rapidity of the growth of the protozoa.

The viability of *Vibrio cholerae* has also been investigated by Houston, using the same technique as for *Eberthella typhosa*. Ninety-nine per cent of the cholera organisms perished in three days under the laboratory conditions of the experiment. This is a much shorter period than required for *Eberthella typhosa*. Gelarie⁴⁷³ studied the longevity of *Vibrio cholerae* in water of New York Bay. He stated that the survival of these organisms in water depends upon the strain which is used, the number of bacteria seeded, and other factors. The organisms were said to live in native bay water from seven to 45 days, and in sterilized bay water up to 285 days. In sterile tap water they lived for one to 18 days, and in native tap water from one to three days. In competition with the other water organisms the life of the cholera organisms was found to be short. Yasuhara⁴⁷⁴ made

tests on the longevity of Yamamoto and Yamashita strains of cholerae vibrio in five different kinds of water by infecting 200-ml. portions and storing them outdoors, but shielded from the direct rays of the sun. The 1:00 A. M. temperature varied from 1 to 5°C. (33.8 to 41°F.). The type of water and the time of survival of the cholera organisms follows: (1) Sea water, Waka-no-ura Bay, 11 days; (2) mixture of sea and river water, Estuary water at Aogishi, 13 days; (3) river water, Kinodawa River, eight days; (4) tap water, Wakayame City water works, eight days; (5) well water, well at laboratory, eight days. It was suggested that if water is known to be contaminated with cholerae vibrio in winter, its use be suspended for at least two weeks. It was thought that this would give an ample margin of safety.

That generalizations should not be made is evident from experiments conducted by Moens⁴⁷⁵ who found that the type of water was important. Presence of certain species of protozoa is also responsible for more rapid disappearance of *Eberthella typhosa*.

Mycobacterium tuberculosis. Possibility of dissemination of tuberculosis among human beings by water has not worried health officials. Briscoe⁴⁷⁶ observed that tubercle bacilli could live more than a year (441 days) in running water. No difference in longevity of the human and bovine types could be noticed. Briscoe stated that water infected with *Mycobacterium tuberculosis* might infect man and that infected watering troughs might cause the disease in animals. Longevity of this organism was also shown by Brown, Petroff, and Heise⁴⁷⁷ in river water infected by sewage. Viable acid-fast bacteria were found 2.9 miles down stream from the sewer outfall. They quoted Jessen and Rabinowitch,⁴⁷⁸ who found the organisms 100 meters below a sewer outlet. Laboratory experiments have also shown appreciable longevity, especially in the dark. In Rhines' experiments, a strain of *Mycobacterium tuberculosis* (avis) was alive in both sewage and water after 93 days.

Tularemia from Water. Infected rodents are the usual sources of infection of tularemia. Karpoff and Antonoff⁴⁷⁹ reported that it could be spread by water. The quantity of microorganisms in the infected water courses may sometimes be so considerable that their isolation does not meet with great difficulties. One hundred per cent of the guinea pigs infected with the water died and their organs showed characteristic pathological-anatomical changes. From the organs of all the guinea pigs were obtained cultures of *Pasteurella tularensis*. The cultures isolated from water did not differ in regard to virulence from those that were isolated from the suppurated lymph glands of patients. When these cultures were tested on guinea pigs, death followed in 100 per cent of cases and the organs showed changes characteristic of tularemic infection.

479. Karpoff and Antonoff. 1936. J. Bact. 32, 243-258.

Leptospira in Water. Hindle⁴⁸⁰ found in London water an organism morphologically identical with *Leptospira icterohaemorrhagiae*. He could not isolate it in pure culture. Guinea pigs which were inoculated with water containing the organisms died. Hindle believed that spirochetal jaundice may be added to the list of diseases which may be disseminated by bad water. Bauer,⁴⁸¹ by using a special medium, was able to isolate 12 strains of *Leptospiras* from 29 samples of water collected. He also obtained a number of different kinds of *Spirochaetes*. After Hindle's report, Houston of the Metropolitan Water Board, in the 20th Annual Report, was led to study the presence of *Leptospiras* in water. He reported their presence and studied the pathogenicity of certain strains which he isolated.

Tracing Pollution in Water Courses. Several methods have been used as well as different materials, such as sodium chloride, lithium salts, fluorescein, cultures of *Serratia marcescens* (*Bacillus prodigiosus*), etc. Sanitarians frequently find it necessary to resort to one of these methods to determine the origin of pollution in water supplies.

Fluorescein. Dole⁴⁸² summarized his investigations on the use of fluorescein in the following statements: 1. In determining the sanitary value of a well or spring it is more important to study the underground flow than to analyze the water itself. 2. Foreign substances put into the aquifer and traced from point to point are of great value in this study. 3. With the fluoroscope one part of fluorescein can be detected in 10 billion parts of water. 4. Fluorescein is a particularly valuable flow indicator for fissured or cavernized rocks. 5. It is also available in gravels, where it has been used with success. 6. It progresses at a slightly lower rate than the water in which it is suspended. 7. It is not decolorized by passage through sand, gravel, or manure; it is slightly decomposed by calcareous soils. 8. It is entirely decolorized by peaty formations and by free acids, except carbonic acid. Trillat⁴⁸³ claimed that fluorescein could be detected in dilutions of one part in 2,000,000,000 but that before the dye is used a study of the soils should be made with regard to the presence of matters which decompose it. Marboutin⁴⁸⁴ came to somewhat similar conditions. Martel⁴⁸⁵ showed that fluorescein, even in very concentrated solutions, decolorizes rather quickly after being kept in the sunlight. When it was kept in complete darkness, which would be the case in the earth, it did not change even after long periods. An anonymous article in the *Engineering News-Record* stated that one part of fluorescein in 40,000,000 parts of water may be detected with the naked eye and one part in 10,000,000,000 by means of a long glass tube. McCrae and Stokes⁴⁸⁶ used fluorescein to good advantage for determining the source of *Escherichia coli* in wells. It was found that swamp water was getting into the wells through a fissure in the rock. It was shown that fluorescein penetrates soil and that it is devoid of harmful effects in the amounts used.

Uranin. Stiles, Crohurst, and Thomson⁴⁸⁷ used the dye uranin for tracing the movement of water through sand. The conditions which would have to obtain would probably be quite like those for fluorescein.

***Serratia marcescens* (*Bacillus prodigiosus*).** This organism was found to be an unreliable indicator since it so easily lost its red pigment-forming ability according to Hilgerman.⁴⁸⁸

Gehrmann⁴⁸⁹ reported that Alba Orlandi and Roudelli, who used a suspension of *Serratia marcescens*, found that cultures of this organism poured on the ground passed through soil 200 meters, and Pfuhl found that it took the same organism a short time to pass through 24 feet of gravel. Gehrmann also reported a place at which wells, 200 to 300 feet deep, too near an old canal, were subject to entrance of contaminated water; no experimental data were given. *Serratia marcescens* was used on a large scale in the famous litigation between the City of St. Louis and the State of Missouri against the City of Chicago and the State of Illinois, over the pollution of the Illinois River with Chicago sewage. One hundred or so barrels of a broth culture of *Serratia marcescens* were poured into the drainage canal in order to show that objectionable bacteria might pass down the Illinois River and reach the intake of the St. Louis water supply.

Sodium Chloride. Salt was used by McCallie,⁴⁹⁰ in Georgia, for the purpose of demonstrating the effects of discharging sewage into deep wells. A large amount of salt was put into a 124-ft. drilled well and the content of chloride in the water of the surrounding wells was determined. Increased content of chloride showed that there was underground connection between the wells and springs in the vicinity. Tanner⁴⁹¹ tried to use sodium chloride to determine how apparent pollution was reaching a city water supply in Illinois.

CHAPTER 5

MICROBIOLOGY OF MILK

Milk is an ideal substance for development of bacteria. It has adequate amounts of water, protein, and sugar. Bacteriologists use it in the laboratory as one of many culture fluids. The Milk Ordinance and Code of the United States Public Health Service¹ defines milk as follows: *Milk is hereby defined to be the lacteal secretion obtained by the complete milking of one or more healthy cows, excluding that obtained within fifteen days before and five days after calving, or such longer period as may be necessary to render the milk practically colostrum free; which contains not less than eight per cent of milk solids not fat, and not less than three and one-fourth per cent of milk fat.*

Reaction of Milk. Since the work on hydrogen-ion concentration, much progress has been made in knowledge of the reaction of milk. Milk is amphoteric to litmus.

Baker and van Slyke² found that the hydrogen-ion concentration of over 300 samples of fresh milk varied between pH 6.5 and 7.2. In 80 per cent of the samples it was more than pH 6.76. In general, the reaction of the milk from different quarters of the udder was the same. One hundred and sixty determinations of the hydrogen-ion concentration of fresh goats' milk gave a variation of pH from 6.7 to 6.4, the average being 6.53. Fresh goats' milk is somewhat more acid than fresh cows' milk and much more acid than human milk.

After determining the hydrogen-ion concentration of good, fresh milk, Baker and van Slyke attempted to use determinations of hydrogen-ion concentration for measuring undesirable changes in milk. They attempted this with brom-cresol-purple and stated that the color of this indicator was made lighter by acids, and by heating the milk above the usual temperatures of pasteurization. The color became darker in milk from diseased udders, watered or skimmed milk, or milk to which alkali salts had been added. A test for keeping quality could be made with a specimen collected under sterile conditions. This work was continued by Baker and Breed.³ Decreased acidity in fresh milk was explained by infiltration of blood serum into the milk as secreted. A fairly close relationship was observed between decreasing hydrogen-ion concentration and increase in the number of leucocytes. Golding⁴ used this method for detecting abnormal fresh milk. Sjollesma and van der Zande⁵ reported that milk from diseased udders did not differ from that from healthy udders. They believed that the leucocyte test was valuable. Baker and van Slyke⁶ also studied the

reaction of milk and the bacterial count. Of 570 samples examined, 16 gave a lighter color than normal, of which 11 were found to contain over 10,000,000 bacteria per ml. These data suggested that the hydrogen-ion concentration of milk as determined with brom-thymol-blue could be used as a criterion of quality.

The Cooledge Brom-Thymol Blue Test. Another colorimetric method for determining hydrogen-ion concentration of milk as a method of control was proposed by Cooledge and Wyant,⁷ Cooledge,⁸ and Cooledge and Goodwin.⁹ They suggested use of brom-thymol-blue under different conditions than those used by Baker and van Slyke⁶ with brom-cresol-purple. They studied the rate of change of hydrogen-ion concentration of a brom-thymol-blue broth solution due to the bacteria and enzymes in .1 ml. of milk. The culture tubes were incubated at 37°C.(98.6°F.) and observed hourly for changes in pH values. With the same indicator, Schultz *et al.*¹⁰ reported that where hydrogen-ion concentration was high, the bacterial counts were also high. At pH 6.6 the bacterial counts were high, averaging 16,000,000 and 100,000,000 bacteria per ml., at pH 6.5. These results were confirmed by Cooledge.⁸ Schultz, Marx, and Beaver¹¹ applied the Cooledge test to market milks. The counts increased rapidly from about 3,000 per ml. with a pH of 6.8, to 100,000 with a pH of 6.5. Further increases in acidity were not accompanied by increase in counts. Acidity was not detected by taste until it had reached pH 6.0. Hastings and Davenport¹² did not find this test to be as reliable as the reductase test. On account of the interest in hydrogen-ion concentration methods for determining the sanitary quality of milk, Sommer and Hart¹³ tried to determine whether the presence of acids in the ration of the cow influenced the reaction of the milk. Even 120 ml. of concentrated sulfuric acid a day did not alter it. This would seem to indicate that presence of acids in rations of the cow would not affect the pH methods of determining milk quality.

Cooledge,¹⁴ comparing the bacterial count and changes in hydrogen-ion concentration, reported that the pH method seemed to be best for determining old milk. He believed that the pH score was more efficient in detecting slight changes in the milk than plating methods. The per cent efficiency of the methods as a whole in detecting slight changes in the history of the samples was as follows: In samples with bacterial count under 25,000, 45.8 per cent; between 25,000 and 100,000, 71.4 per cent; between 100,000 and one million, 85 per cent, and in samples with bacterial counts over one million, 97 per cent. The medium giving the highest average counts depended upon the predominant groups present in the sample studied, perhaps accounting for the divergent results obtained by

various workers. In 81 comparisons of the pH score with results of the reductase test and bacterial plate counts, the pH score checked as well with the number of bacteria per ml. as did the reductase rating, although neither is an absolute measure of the bacterial content. Devereux¹⁵ reported good correlation between the brom-thymol-blue test and the methylene-blue reduction test. This work related the Cooledge test with another which is quite widely used in milk-control work.

Brom-Thymol-Blue Test in Milk (Cooledge and Wyant⁷). The technic and apparatus for this test were outlined in a bulletin from the Digestive Ferments Company. The following has been adapted from that bulletin:

Preparation of Media. Prepare in one flask, only as much medium as will be used in one test, by dissolving in the proportion of 1.8 grams Bacto Cooledge Broth, Dehydrated, in 100 ml. distilled water. Sterilize in the usual manner and store in the ice box. Larger quantities may be made, sterilized, and stored in flasks until needed.

When ready to use, check color to be sure the medium has a pH value very close to 7.0. This is done by removing 10 ml. with a sterile pipette into a sterile 1.8 x 16 cm. test tube, and comparing with the standard tube pH = 7.0 in the comparator. Broth without indicator should be used as a compensating blank. See *Preparation of Compensating Blanks*. A few drops of N/1 NaOH or HCl are then added if necessary.

This procedure is given only for emergency as no adjustment should be necessary.

The sterile broth is then transferred in 10 ml. portions to sterile 1.8 x 16 cm. test tubes, using a sterile 10 ml. pipette.

Preparation of Compensating Blanks. To 100 ml. of ordinary nutrient broth is added one ml. of milk. This is distributed in 10 ml. portions in 1.8 x 16 cm. tubes and subsequently sterilized for 20 minutes at 15 pounds. These tubes may be held in the ice box for use. A few tubes of broth without indicator should be sterilized and stored for use as compensating blanks in adjusting pH of broth under *Preparation of Media*.

Preparation of Samples. The same care should be exercised in sampling milk for this test as is used in any other method. The test calls for the addition of .1 ml. milk to each tube of Cooledge Broth, but to reduce errors incident to this small measurement it is recommended that one ml. of milk be added to nine ml. of sterile dilution water, and one ml. of this mixture be added to the sterile Cooledge Broth.

If this medium is not available one may prepare his own medium as directed in the chapter on "Media."

Incubation. After the milk has been added the tubes are placed in a water bath or incubator at 37°C. (98.6°F.). Observations are made every hour to detect the first color changes due to activity of bacteria or enzymes in the sample. As soon as pronounced changes are noticed, hourly readings are made by placing the tubes containing the samples in the comparator and comparing with the standard tubes which are described below. Tubes must be cooled to 20°C. before readings are made, as it is quite necessary to have all readings made at a constant temperature.

Standards. The standards are the buffer solutions described by Clark and Lubs. Ten ml. portions are placed in the same 1.8 x 16 cm. tubes and .8 ml. of a .04 per cent aqueous solution of Brom Thymol Blue is added. The tube is then sealed and may be kept for a considerable period. The standards used in this test must have the following readings: pH 7.4, 7.2, 7.0, 6.8, 6.6, 6.4, 6.2, 6.0, and 5.8.

Wilson¹⁶ observed that decoloration of the broth did not occur uniformly. While the lower part of the broth became yellow, the upper part remained blue. He found that sometimes the blue color was confined to the top and in some of the tubes the whole upper half might be blue. Consequently, readings of pH were unsatisfactory. Again, several tubes,

15. Devereux. 1929. J. Dairy Sci. 12, 367-373.

16. Wilson. 1935. Med. Res. Council, H. M. Stat. Office, p. 302.

after commencing to turn acid, reverted to alkaline and then once more became acid. The time required by these tubes to reach a pH of six was abnormally long. The experience of Wilson confirms that of others.

Souring of normal market milk is a complicated process subject to many different conditions. One of the most important is bacteria other than those which produce the acid. Cox and Whitehead¹⁷ followed the action of four organisms commonly found in contaminated milk. *Escherichia coli*, *Bacillus subtilis*, a staphylococcus, and *Bacillus fecalis alkaligenes* were grown in milk with lactic streptococci and the acidity produced in a given time was determined. *Bacillus subtilis* appeared to stimulate acid production. *Escherichia coli* caused a decrease in acid production in some experiments and an increase in others. The staphylococcus had a slight stimulative effect. *Bacillus fecalis alkaligenes* had only a slight effect, which was barely beyond experimental error. Brown¹⁸ had also reported similar results.

Influence of Climatic Conditions on Souring of Milk. Milk sours so often during hot humid periods with thunderstorms that the change has been attributed to the lightning or thunder. Tolemei,¹⁹ after subjecting fresh milk to currents of electricity of different intensities, found that, instead of hastening souring, it was actually retarded in some cases. Further experiments seemed to convince him that ozone formed by the electric current caused curdling. Gerstmann²⁰ claimed that lightning caused induction currents in the milk which decomposed the constituents soluble in water. Acid, suddenly formed in this manner, curdled the milk. Trillat²¹ believed that reduced air pressure of thunderstorms caused the

development of gases which promoted growth of bacteria. High temperatures and humidity were said to favor the development of bacteria. Wernicke²² also believed that the climatic conditions favored development of bacteria; his explanations were not very definite.

Relation of Bacterial Content of Milk and the Amount of Acid Formed.

It was formerly believed that delay occurred in the formation of lactic acid by bacteria in milk. That a lag phase existed during which no acid was formed had been observed. Revis and Payne,²³ for instance, suggested that bacteria in milk developed ability to produce acid only after a certain period of growth. Such opinions are not held today. No reason in the first place obtains for assuming that acid is not formed at all phases of growth of bacteria in milk. During the early phases so little is formed that the biochemical methods used for its detection are not delicate enough. Rahn²⁴ and Baker, Brew, and Conn²⁵ computed the acid that might be formed by an average single cell in milk. In general, a fairly definite ratio existed between the acid produced and the number of bacteria. Heinemann²⁶ and Barkworth, Mattick, Taylor, and Williams²⁷ were able to show close relationship between temperature, numbers of bacteria, and amount of acid.

The types of bacteria are important. Some which are unable to attack lactose might develop without forming much acid. Schmidt²⁸ observed that production of acid in milk proceeded more rapidly at the surface than in the deeper layers. Cells of *Streptococcus lactis* were 85 times more numerous at the surface than in the deeper layers. It is readily seen that the question of relation of amount of acid formed to the number of bacteria present is an intricate one. Many factors are involved. In general, there must be a fairly close relationship, because acid is a product of metabolism. The greater the number of bacteria, the greater would be the amount of acid formed.

Coagulation by Rennin. It was believed for a long time that coagulation of milk was due only to acid. Fremy, in 1839, supposed that a special enzyme was present in the lining of calves' stomachs which formed acid from the lactose. Hammarsten proved that the production of acid from lactose was not the cause of coagulation by rennin, but that it was brought about by a special enzyme, which acted directly on casein.

The action of rennin is proteolytic, since it destroys casein. It might be regarded as a preliminary process in digestion. Bosworth²⁹ stated that probably the action attributed to rennin may be produced by any proteolytic enzyme. In the bacterial world, it has been known for some time that an organism which will split casein will also probably split gelatin and other proteins.

"Sweet curdling" of milk causes considerable trouble in the dairy industry. Evaporated milk is frequently curdled by bacteria which form little or no acid, but which are able to thoroughly coagulate the proteins. Hammer³⁰ believed that these organisms were identical or closely related to *Bacillus subtilis*. Some evidence exists to show that the trouble is not always bacteriological.

Measurement of Volume of Cream on Milk. Harding³¹ proposed the following method for measuring cream volume. The method of measurement consisted of filling round-bottomed test tubes, one inch in diameter, to a depth of 204 millimeters (8 inches) with the milk to be tested. These tubes of milk were immediately cooled in ice water; and when cool, were held at 4.5°C.(40°F.) for approximately 24 hours. The depth of the resulting cream layer was measured in millimeters, and each millimeter of cream represented .5 per cent of cream by volume. The volume of cream as determined in this way agreed closely with the volume of cream developed in milk bottles under similar temperature conditions. Dahlberg and Marquardt³² used 100 ml. graduated cylinders and found them to be just as satisfactory as Harding's tubes.

Methods for Detecting Heated and Raw Milk. Food-control officials found it necessary to determine whether milk has been heated; for instance, city ordinances prescribe that milk shall be pasteurized. Laws in some countries demand that skimmed milk and buttermilk be heated to at least 85°C.(185°F.) before sale. It was for the administration of this law that Storch devised a method based on Babcock's discovery that fibrin in milk decomposes hydrogen peroxide, that cream is more active in this respect than whole milk, that skimmed milk is less active, and furthermore, that milk heated to 100°C.(212°F.) loses this property. Storch found that milk retained its property of reducing hydrogen peroxide up to 79°C.(174.2°F.). Grimes³³ improved Storch's technic. Other methods have been suggested by Bernstein,³⁴ Wilkinson and Peters,³⁵ Balaz,³⁶ Frost,³⁷ Hekma,³⁸ and van Slyke and Keeler.³⁹ The most recent and probably the best is the phosphatase test described in the chapter on "Pasteurization of Milk."

Duke's⁴⁰ Bacteriological Test for Pasteurized Foods. This method rests on the preparation of curves, showing the relation between the proportion of microorganisms surviving, and the temperatures to which these have been subjected. They are used to determine whether a solid or liquid has not, or has been pasteurized, and if the latter, at what temperature this was conducted. The test has been applied to milk and cheese, and should be adaptable to a wide range of products. The liquid under examination is well shaken to ensure an even distribution of the organisms present, and about five ml. are added to each of six sterile test tubes. One of these is kept at the ordinary temperature, while the remainder are placed in separate water baths at 50°C.(122°F.), 55°C.(131°F.), 60°C.(140°F.), 65°C.(149°F.), and 70°C.(158°F.) for 30 minutes. From each tube, one ml. of liquid is transferred to a tube of nutrient agar culture medium at 50°C.(122°F.) and dilutions of 1-10 and 1-100 are treated similarly, each portion of

the inoculated medium being poured into a Petri dish, allowed to set, and incubated at 37°C. (98.6°F.) for three days. The numbers of colonies are then counted on each plate and the average of the three heated to the same temperature is taken and expressed as a fraction of the colonies developed from the unheated liquid calculated to 1,000. A curve is then drawn with the ordinates representing the number of colonies and the temperatures to which the liquids have been heated as abscissae. In the case of unpasteurized materials, the curve shows a steep decline immediately followed by an almost horizontal portion, while pasteurized foods in general, yield a curve rising irregularly to the pasteurizing temperature with a steep decline beyond this point. To avoid errors, owing to dilution, Duke is experimenting with Petri dishes nine inches in diameter, using 250 ml. of agar culture medium for each, and inoculating this with one ml. of the undiluted heated liquid.

Homogenized Milk. This is milk which has been forced through very small openings under high pressures. It so completely disperses the fat globules that they remain uniformly suspended throughout the milk without forming a cream layer on standing. Dispersion of the casein is also affected, for homogenized milk gives a soft curd in the stomach and is therefore recommended by physicians where curd tension is important.

Homogenized milk is defined in the Milk Ordinance and Code of the United States Public Health Service¹ as follows: "*Homogenized milk is milk which has been treated in such manner that after a storage period of 48 hours tests of the 100 ml. portion decanted from the top of a quart bottle of milk will not show a difference in fat content over tests of the remainder of the milk after thorough mixing exceeding 5 per cent of the total fat content. For example, on 4 per cent milk the difference shall not exceed 0.2 per cent.*"

Relatively poor keeping quality of homogenized milk was one of its first problems, according to Tracy.⁴¹ Bacterial numbers are usually higher in homogenized milk than in milk not so treated. This is due to breaking of clumps as well as pick-up of bacteria in the machine itself. Tracy found that it was possible to homogenize low-count pasteurized milk without materially increasing the count. The average of 13 days' observations showed a count of 1,213 for the milk in the vat and 1,990 for the first homogenized milk and 1,418 for the milk last homogenized. Fewer bacteria were reported to be present in pasteurized homogenized milk than in regular pasteurized milk by Hollingsworth⁴² of the Canadian Health Department. Homogenization apparently permits a more efficient heat treatment; greater efficiency is thus obtained in the pasteurization process and more bacteria are killed.

BACTERIA IN MILK

Before bacteriological methods may be used for determining quality of milk, it is necessary to know the origin of bacteria which are found in milk. Unless these are known, proper interpretation of results of bacteriological analyses are not possible. Bacteria in milk are of interest for several reasons. They are used as indices of undesirable conditions of production by both health officers and research workers who are seeking more information about milk itself. It is necessary to know the reasons

for high plate counts in milk if they are to be used in control of milk supplies.

Influence of Bacteria on Body of Cow on Number of Bacteria in Milk.

At one time the surface of the cow was considered an important source of bacteria in milk. Consequently every attempt was made to prevent dirt from falling into the milk pail. Experiments carried out to determine the real origin of bacteria in milk showed that too much emphasis had been placed on the cow and her environment. Esten and Mason⁴³ reported that a gram of powder obtained by currying a cow was found to contain 207,000,000 organisms. Despite such results later work indicated that utensils were the source of the great majority of bacteria.

Relation of Barn Conditions to Bacterial Content of Milk. Early dairy bacteriologists looked upon conditions in the barn as important sources of bacteria in milk. Important among them was barn air and the general construction of the stable. These various factors were studied at the New York and Illinois Agricultural Experiment Stations. Ruehle, Wilson, and Smith⁴⁴ probably were among the first to study the question seriously. They found that the importance of barn construction had been considerably overestimated and that, within rather wide limits, the condition of the stable exerted no measurable influence upon the bacterial content of the milk produced in it. Clipping the udder, flank, and adjoining portions of the cow seemed to increase rather than decrease the number of bacteria in the milk. The effect of brushing and combing at the rate of two cows per minute was practically the same as treatment with the vacuum cleaner at the rate of one cow per minute. When all utensils had been carefully steamed, cooling and straining the milk resulted in only a small increase in germ content, even when this was done under unfavorable conditions.

Another factor in the barn to which dairymen had always given considerable attention was the air. They were accustomed to feed after milking in order to avoid as much dust as possible during milking. Experiments again revealed that stable air contained few bacteria. Ruehle and Kulp⁴⁵ found that there were between 50 and 200 bacteria per liter in barn air during such barn operations as milking and feeding. When sterile water was "milked" in the station stable from an apparatus designed for the purpose, the bacteria in the liquid averaged only 12 per ml. with a maximum of 73. When a heavy dust was raised in the stable loft, the number of bacteria in the air was usually between 1,000 and 2,000 per liter. Under such conditions sterile water "milked" had an average bacteria content of 47.6. Ruehle and Kulp stated that between 100 and 1,000 cells per ml. would be added to milk when it was secured under very dirty conditions. It may be recalled that Winslow and Browne⁴⁶ reported the average number of bacteria in country air to be 56, in city street air 72, in office air 94, in factory air 113, and in air in school rooms 96 per cubic foot. Such data would indicate that bacteria are no more prevalent in

stable air than in the air of many other places. Results of investigations just reviewed would not justify indifference to the question of dust in the stable during milking. Earlier investigations than those just reviewed, Stocking's⁴⁷ for instance, showed a contribution of bacteria by dusty feeds while the cows were being milked which might, under some conditions, be significant. They might be significant if objectionable bacteria are contributed.

Prucha and Weeter,⁴⁸ studying the same problems, worked in three dairy barns of widely different degrees of cleanliness. Study of these three barns showed that even under wide extremes in barn conditions, it was possible to produce milk with fewer bacteria than 10,000 per ml. In a total of 1,665 samples taken from 138 cows during 1914 and 1915, the number of bacteria varied from three to 218,560 per ml. when determined by the standard agar plate. The average bacteria content of the milk from individual cows was low, but one cow was found whose milk showed a relatively high average of 35,131 bacteria per ml. The average bacteria content of the milk was over 10,000 only once in Barn I, only twice in Barn III, and in Barn II the highest average was only 2,224. These barns were two extremes in cleanliness. One was allowed to become very dirty, typical of what a dairy barn should not be. The other was what a dairy barn should be. The results of these investigations showed that factors other than barn conditions were responsible for the bacteria in milk.

Normal Bacterial Flora of the Udder. Investigations on the various sources of bacteria in milk logically start with the cow herself. As far as she is concerned, two possible sources exist, the udder interior and the exterior surface of her body. Very early in the history of bacteriology, milk was said to be sterile when it came from the udder. Chief among the proponents of this view was Lister, who assumed that the bacteria which he found were contaminants. Schulz,⁴⁹ however, reported that freshly drawn milk was not sterile and that a considerable number of bacteria might be present in first drawn milk. Toward the end of the milking period, however, the number might become smaller. The first portion of milk from a cow contained 50,556 bacteria per ml. when precautions were taken to rule out contaminating bacteria from the milker's hands, etc. Schulz and Barthel believed that bacteria might grow into the teat and that they were largely washed out during milking. Backhaus and Cronheim⁵⁰ believed that even with milking tubes, it was impossible to obtain sterile milk from the cow. Schulz's results were also confirmed by Moore,⁵¹ who used the milk of nine cows. He believed that the characteristics of bacteria in milk were more important than were numbers. Ward²⁵ and Moore, after further study, again in 1902 arrived at similar conclusions.

52. Ward. 1898. J. Appl. Micros. 1, 205-208; N. Y. Agr. Expt. Sta. Bull. 178.

The problem was attacked by Uhlmann⁵³ from another angle. Examination of over 800 sections of the teats of 35 cows revealed the presence of bacteria. Similar technic was used by Ward,⁵² who examined the glandular tissue of apparently healthy udders of six cows, together with the foremilk just before they were slaughtered. He found that the same organism frequently occurred in the foremilk and in each of the three parts of the udder. D'Heil,⁵⁴ finding bacteria regularly present in the milk cistern and ducts, concluded that they gained entrance through the orifice of the teat. Glandular tissue which contained but a very few bacteria was believed to be bactericidal. Considerable attention has also been given to the types of bacteria found in fresh milk collected under carefully controlled conditions. Esten and Mason,⁵⁵ in the milk from a herd of 25 cows, found over 50 different species of bacteria. Over half of them had no effect on sterile milk when inoculated in pure cultures. Harrison and Cumming⁵⁶ reported a rather heterogeneous flora of bacteria in the udder and were not alarmed by the large number of bacteria which were found. Freudenreich's⁵⁷ experiments were carried out with every effort to rule out air contamination. Harrison and Savage⁵⁸ also reported the presence of bacteria in udder milk.

About this time a series of experiments was undertaken at the New York Agricultural Experiment Station, results of which answered many questions on origin of bacteria in milk. Harding and Wilson⁵⁹ reported an average of 428 bacteria per ml. in 1,230 samples of udder milk. Various factors, such as the age of the cow and the quarter of the udder from which the milk came, were suggested to be important influencing factors. A few years later Harding and Prucha,⁶⁰ from a similar investigation at the Illinois Agricultural Experiment Station, reported 964 bacteria per ml. in milk direct from the udder. The average number of bacteria per ml. per cow showed variation from 329 to 1,868. In some cases the milk from the same cow showed considerable variation in numbers of bacteria. In another investigation at Geneva, N. Y., Dorner⁶¹ examined 993 samples of aseptically drawn milk from 132 cows in six herds, using standard agar plates, by the Burri quantitative film culture technic. The calculated average bacterial count of the milk from each herd showed great variations, the lowest obtained on Burri slants being 3,965 per ml., the highest 9,635 per ml., and the average 7,475 per ml. On standard agar plates, the average counts from individual herds varied between 530 and 4,390 per ml., the final calculated average being 2,775 per ml. It appears that a small number of samples containing relatively high numbers of bacteria is usually the source of the greater part of the bacteria in aseptically drawn milk. Dorner,⁶¹ later at Liebefeld, Switzerland, reported an average bac-

terial content in fresh milk of 3,099 per ml. In South Dakota, Copeland and Olson⁶² had previously found some 1,541 bacteria per ml. in fresh milk. Examination by the microscope method of 88 aseptically drawn samples of milk by Thornton and Strynadka⁶³ revealed the presence of many more bacteria than have just been reported. The average was 25,000 per ml. in 29 milks containing not over 500,000 leucocytes and 81,000 in 53 milks containing over 500,000 leucocytes per ml. That the microscope method showed more bacteria is to be expected.

Effect of Inoculating Bacteria Into the Udder and Feeding to the Cow.

Demonstration of the presence of bacteria in milk from normal animals suggested to investigators a study of the behavior of saprophytic bacteria injected into the udder. Following injection of pure milk cultures of *Aerobacter aerogenes* into the udder, Appel⁶⁴ noticed swelling of the teats and marked changes in the milk. Injections of sterile milk and water, however, did not cause such results. Another experiment carried out by Pernot,⁶⁵ sought to determine whether bacteria commonly found in stagnant water could gain access to the milk supply through the cow. Pure cultures of *Pseudomonas fluorescens*, *Chromobacterium janthium*, and *Bacillus ramosus* were in turn added to the drinking water and given to a cow every morning for periods of 10 days. In no case were the bacilli found on plate cultures made from the milk each morning and evening. *Bacillus ramosus* was administered in cultures containing spores in abundance but was not found in either the milk or excreta. The same cow was then given each morning, for 10 days, 10 ml. of a bouillon culture of *Eberthella typhosa*, and for the five days following, 20 ml. of the culture without apparently affecting the health of the cow. In only two cases did colonies of *Eberthella typhosa* develop on plate cultures made each morning and evening from the milk, urine, and feces, and these were considered accidental inoculations. To determine whether *Eberthella typhosa* could enter the udder through the milk ducts, the teats were immersed in a pure culture, directly after milking and allowed to dry spontaneously. Twelve hours later the teats were disinfected and plate cultures made from the milk drawn under aseptic precautions. The experiment was repeated for five days; in no instance, during the experiments, or for a number of days after did cultures show presence of *Eberthella typhosa*. Similar experiments were made by Russell and Hastings⁶⁶ with *Bacillus acidi lactici*, an acid-producing liquefying bacillus isolated from Cheddar cheese, *Serratia marcescens*, and a yellow liquefying coccus isolated from foremilk. Agar cultures of these organisms were transferred to distilled water or normal salt solutions and introduced into the udder through a milking tube. The results furnished no evidence of the growth in the udder of any of the species used. In nearly every instance, the milk became abnormal, and occasionally the udder became inflamed and tense,

showing production of temporary garget. Ward⁵² injected *Serratia marcescens* by means of a hypodermic syringe lengthened with a milking tube. He was able to find the organism in the milk for five days after its introduction, although it decreased regularly and disappeared on the sixth. Harrison and Cumming⁵⁶ inoculated udders with *Serratia marcescens*, *Bacillus exigum*, and *Pseudomonas fluorescens* by smearing the ends of the teats with cultures. The bacilli soon disappeared from the milk. Cultures were made from the livers and udders of three cows which had been dry for several weeks previous to slaughter. Bacteria were found in the livers of all three and in the udders of two cows. While the results are not considered sufficient to warrant a positive assertion they point toward infection by way of the blood or lymph rather than through the teat.

The experiments reported above involved nonpathogenic bacteria, but do show that bacteria can live for some time in the udder. They probably gain entrance in different ways. Similar experiments with pathogenic bacteria are reported elsewhere in this chapter.

Results of post-mortem examination of the udder must be interpreted with care. Curran⁶⁷ found that some bacterial types maintained in the udders of living cows at a fairly constant numerical level multiplied with great rapidity immediately after death and removal of the blood. Rapidly growing invasive types of streptococci were most affected. The udder floras of some cows did not increase appreciably during the post-mortem incubation period. Relatively inert, slow-growing micrococci and streptococci usually comprised this group. The suddenly increased multiplication of the udder flora that frequently attends withdrawal of the blood suggests that the circulatory system is directly or indirectly associated with the formation of the bactericidal substance in milk.

Relation of Utensils to Number of Bacteria in Milk. Failing to find among barn conditions explanations for the number of bacteria in milk, dairy bacteriologists continued their search for the answer. Since unsterile utensils were found to contribute most of the bacteria, many investigations have been carried out to learn how they should be handled. Pease⁶⁸ claimed that, where high counts had been obtained in a dairy which had operated for a long time, they were due to inefficiently cleaned apparatus, and incubation of bacteria occurred on moist surfaces of the cans, pails, etc. Prucha, Harding, and Weeter⁶⁹ reported some interesting data to substantiate this contention of Pease. With sterile utensils and sterile bottles, milk leaving the barn was found to contain 2,588 bacteria per ml. and the bottled milk 3,875. Where the utensils were simply washed and with only the bottles sterile, there were increases of 57,077 due to the pails, of 15,353 up to the clarifier, of 172,763 due to the clarifier, of 19,841 due to cooler and of 247,611 due to the bottler. Ayers, Cook, and Clemmer,⁷⁰ in a careful study of the factors involved in the production of a milk of low bacteria content, state as follows: "Three simple factors were

67. Curran. 1931. J. Infect. Dis. 48, 408-412.

68. Pease. 1916. Amer. J. Pub. Health 6, 563-568.

necessary for the production of milk with a low bacterial content, namely, sterilized utensils, clean cows with clean udders and teats, and the small top pail." A fourth factor, holding the milk at a temperature near 10°C. (50°F.) or lower, is necessary in order to keep the bacterial count low. Even cow manure was found to be of less importance in influencing the bacterial count than utensils. Prucha, Weeter, and Chambers⁷¹ reported data which leave little doubt that the utensils are the important agents contributing bacteria to milk. This was strikingly illustrated by one experiment. When all of the utensils at the barn and in the dairy were thoroughly steamed, the bottled milk had uniformly only about 5,000 bacteria per ml. but when steaming was omitted the bottled milk frequently had 100,000 bacteria per ml. These authors stated that too much stress had been in the past laid on procedures which were of minor importance. According to Whiting,⁷² the clumps of bacteria in milk noticed during examination with the microscope are due to utensils and not to growth. A study of 3,600 samples of unpasteurized milk showed clumps averaging 26.8 individuals per clump, the clumps decreasing in size as the total number of bacteria increased. Berry⁷³ also found that the dairy utensils were a more probable source of contamination of milk than dirty cows, dusty stables, or other imperfections in milk production. Sterilization of cans, for instance, increased the keeping quality of the milk between 20 and 30 per cent. Micrococci have been found to be especially prevalent in dairy utensils. Whiting⁷² found them to be common on the dairy apparatus which he studied. Robertson⁷⁴ explained their prevalence on the fact that they survive the sterilizing procedures better than the other bacteria. Prucha and Harding⁷⁵ stated that the container could contribute as many as 100 bacteria per ml. without detriment to the milk, with which Proctor and Hoy⁷⁶ did not agree. They believed that not more than five cells per ml. should be allowed.

Construction of the milk pail has been found to influence the number of bacteria in milk. The smaller the top of the pail, the fewer bacteria reach the milk. This was nicely shown by Harding and Prucha⁷⁷. In every case, considerably fewer bacteria were found in the milk collected in the closed-top milk pail. They reported that a small-top pail reduced the amount of dirt from 20 to 45 per cent over that getting into the milk when an open-top pail was used. As stated above, Ayers, Cook, and Clemmer⁷⁰ mentioned the small-top pail as one of the four important factors in the production of milk with a low bacterial count.

The milking machine has also made another opportunity for milk to pick up bacteria from utensils. The earlier literature on the subject has been reviewed by Ruehle, Breed, and Smith.⁷⁸ Investigations by Robert-

son,⁷⁹ Bright,⁸⁰ and Breed and Bright⁸¹ have resulted in information which should make the milking machine contribute fewer bacteria to milk. Fisher and White⁸² attempted to use a commercial disinfectant. Large amounts had to be used.

Cleansing and Sterilization of Dairy Utensils. The fact that milk is such a good medium for development of bacteria makes it necessary to keep utensils in which it is handled as clean as possible. It has been found that they should be practically sterile. Prucha and Harding⁸³ and Ayers and Mudge⁸⁴ studied hot air as a method of sterilizing utensils. The former observed rapid development of bacteria in moist utensils. Cans which were quickly dried and kept dry contributed few bacteria to milk. Stewart⁸⁵ and Mattick and Hallett⁸⁶ stated that ordinary washing would not suffice. Drastic methods were necessary to remove bacteria from dairy utensils.

Chemical sterilization with chlorine compounds has become routine practice. Ruehle, Breed, and Smith,⁷⁸ Taylor,⁸⁷ and many others have contributed to the subject. This chemical substance is playing a role in milk sanitation comparable to that played in water purification.

SANITARY CONDITION OF GLASS MILK BOTTLES

While the glass milk bottle made possible vast improvements in marketing fluid milk, its use also introduced new problems in cleaning and sterilization. That these have not been easy to solve is indicated by many publications and committee reports. The main difficulty with the used glass milk bottle is to tell when it is clean, for results of different investigators have shown little relation between appearance of the washed and sterilized bottle and its bacterial content. A committee of the American Public Health Association (Holmquist, chairman)⁸⁸ tried to define clean and sterile dairy utensils. Milk bottles received some discussion. After analysis of results on the bacterial content of washed milk bottles the committee concluded that sterile containers in the surgical sense were not necessary. Sterility was defined as freedom from pathogenic microorganisms and a low number of other types. Barkworth⁸⁹ has also said that sterility in connection with washing dairy utensils makes allowances for a few bacteria. It would be ridiculous to require that *all* bacteria be destroyed when the few which might be left would be harmless. Furthermore, city ordinances frequently permit 30,000 bacteria per ml. in milk. A quart bottle would then receive in the milk placed into it some 29 million bacteria.

Results of various investigations on the bacterial content of washed milk bottles reveal a situation which would not ordinarily be expected. In the committee report referred to above, a state health department is

quoted as finding 22.6 per cent of 1,820 milk bottles containing in excess of 10 bacteria (colonies on plates) for each ml. capacity and 43.1 per cent in excess of one per ml., the standard which has been quite generally accepted in the United States. Layson, Huffer, and Brannon⁹⁰ also reported the bacterial content of glass milk bottles to be quite variable. They said that in any case of 12 bottles, two or three might be sterile while some of the remainder might contain as many as 180,000 to 200,000 bacteria per quart bottle. Some of the large numbers of bacteria might come from bottles which looked clean. Thirty per cent of milk jugs and 14.5 per cent of all bottles showed the presence of gas-forming bacteria. Such results as these indicate that problems relating to cleaning and sterilization of milk bottles have not yet been solved.

Insterility of washed and "sterilized" milk bottles has again been shown by Thomas and Jenkinson.⁹¹ Glass bottles and paper containers taken at random from 24 farms and dairies during summer months showed that the paper bottles had many fewer bacteria than the most efficiently sterilized glass bottles. Hopkins and Kelly⁹² found that supposedly sterile bottles (less than 100 bacteria per bottle) contained from 300 to 160 million bacteria per bottle. They emphasized the danger that might exist in unclean bottles. While large dairies may be able satisfactorily to clean glass milk bottles, the smaller ones may be less efficient, as pointed out by Koch.⁹³ Furthermore, smaller concerns may not have adequate laboratory service to check their procedures. They may be unable to enforce procedures which are known to be necessary whether they be methods involving heat sterilization or chemical substances. Furthermore, some bottles returned to a dairy may have been misused in such a manner that it would be difficult to remove the bacteria even by procedures which would ordinarily result in a satisfactory container. Such occurrences may be prevented by using a single-service container. If the bottle-washer is not operated correctly, Mattick and Hoy⁹⁴ believed that pathogenic bacteria might survive. Milk bottles have been incriminated in spreading communicable diseases. Hunt⁹⁵ observed such infection of a milk supply. Gibbs-Smith and Hobday⁹⁶ infected milk with *Eberthella typhosa* and recovered the organism from two of four bottles after superficial cleaning.

The purging lip may harbor many bacteria. In some cases, according to Dearstyne and Ewing⁹⁷ and Isaacs and Zeiber,⁹⁸ the number may be large. Single caps were found to be less desirable than double ones.

Paper caps have not been used without bacterial examination. Only saprophytic bacteria have been found in them and they are of no sanitary

significance. Paraffining of the discs, according to Rice,⁹⁹ forces the bacteria to the edge, where they may enter the milk more easily.

Bacterial Standards for Washed Milk Bottles and Containers. Bacterial standards have been suggested to determine whether washed and sterilized milk bottles are satisfactory. The "U. S. Public Health Service Milk Ordinance and Code" states that bottles shall be so cleaned that they shall not contribute more than one bacterial cell, or colony, per ml. to milk. The standard adopted by the International Association of Milk Dealers for satisfactory milk bottles was that they should not contribute more than 2,000 bacteria to a quart of milk. Shrader and Craig¹⁰⁰ recommended a standard of not more than 200 bacteria per bottle and that 80 per cent of the bottles of one dealer should conform to it. Parfitt¹⁰¹ would allow 1,000 bacteria per bottle. In England Mattick and Hoy⁹⁴ believed that a standard of over 200 bacteria per bottle could be met by commercially washed bottles. The standard of not over 1,000 bacteria per bottle is generally accepted as good practice in the United States. Hoy¹⁰² later confirmed this opinion.

Bacterial cleanliness of a vessel which has previously contained sour milk will, according to Neave and Hoy,^{102a} normally contain less than 5 million recoverable bacteria per gallon capacity. Such a utensil was considered to be satisfactory when rinsings yielded not more than 5,000 organisms per gallon capacity, and not more than 50 coliform organisms and/or milk souring organisms per gallon capacity.

Levowitz's¹⁰³ Method for Determining Bacteriological Efficiencies of Milk Container Closures. A bacterial suspension of a suitable test organism is frozen into ice. The count of organisms in the ice is determined and this inoculated ice is mixed with normal ice after chopping it fine to yield a standard ice containing a fixed number of bacteria per gram. The organism selected for this work was *Serratia marcescens* and the concentration so arranged that 500,000 cells would be present in a gram of ice. This ice is then used to refrigerate a fixed number of containers, over 100 to reduce experimental errors. The iced containers are exposed to room temperature for four hours without agitation, followed by four hours of intermittent agitation. Such a procedure is comparable to commercial practice. After this the contents of the containers are examined for the test organisms by suitable laboratory methods.

Single-Service Paper Milk Container. The merits of such a container have been recognized for many years. Some health departments have insisted that they be used for homes in which cases of communicable diseases existed. Most of the early proponents, however, allowed economic problems to overshadow the health advantages. Early experience has been reviewed by Kilbourne.¹⁰⁴ These containers appeared on the American market early in the 1920's although they had been proposed many years earlier as very desirable. Relative costs of milk in glass bottles and paper containers have been studied by Bartlett.¹⁰⁵ The single-service container

meets most of the requirements of a satisfactory receptacle for distribution of fluid milk. Health-department officials should encourage use of these containers for their bacteriological condition is vastly superior to that of the glass bottle even after the latter has been cleaned and sterilized by approved methods. It is not necessary to enforce stricter regulations for the single-service paper milk container than for the glass bottle. Contamination from human hands is much less possible with the former than the latter. Prucha¹⁰⁶ summarized the situation as follows:

"When the paper is so made that it is practically sterile, when it and the containers made from it are handled, packed, transported, and stored in such a manner that they will not become contaminated, and then the containers are properly paraffined at 185°F. for 30 seconds or longer, the paper containers will be fully as safe as any container which can be made. When it is remembered that, by the rinse test, the great majority of paper containers yield no microorganisms at all and that the great majority of those which do, show only one or two bacteria per bottle, the ideal package for fluid milk has just about been attained."

Paperboard, from which these containers are made, is made from virgin pulpwood. These containers are not made from chipboard which in turn is made from waste paper. Bacteriological problems in the manufacture of single-service paper milk containers are practically nil. The manufacture of paperboard involves cooking of the pulp at high temperatures, bleaching in strong chlorine solutions, and finally drying at high temperatures on the rolls of the papermaking machine. The United States Milk Ordinance and Code, 1939 edition,¹ stipulates that the stock from which paper containers are made shall not contain over 250 colonies per gram. When the paperboard is made into the final container it is paraffined at temperature which practically sterilizes it. The final product is well within the definition of sterility as it is used in the milk industry. Bactericidal effects of paraffination have been discussed by various investigators (Prucha,¹⁰⁶ Tanner and Lewis,¹⁰⁷ and Moss, Thomas, and Havens¹⁰⁸). The last-mentioned investigators used *Escherichia coli* as a test organism and reported that a mean 99 per cent reduction of the *Escherichia coli* test organism owing to paraffining was obtained in about 10 seconds at 82.2°C.(180°F.), 20 seconds at 79.4°C.(175°F.), 35 seconds at 76.6°C.(170°F.), two minutes at 73.8°C.(165°F.), and four minutes at 71.1°C.(160°F.). These results indicate the greater mean bactericidal efficiency of the higher paraffin temperatures used. If paraffining is to serve as the bactericidal treatment for the surfaces of the paper container, the use of the higher temperatures studied appears essential, unless the immersion times generally used are considerably increased. After considerable study, Rice¹⁰⁹ concluded that most efficient waterproofing is obtained by treating paper containers with a high-melting-point wax, such as 56.1°C.(133°F.) to 57.2°C.(135°F.), applied at the lowest possible temperature, 65.5°C.(150°F.).

The United States Milk Ordinance and Code, 1939 edition,¹ requires that all single-service containers and container caps and covers shall,

prior to use, be given a bactericidal treatment equivalent to contact with paraffin for at least 20 seconds at at least 82.2°C. (180°F.), or for at least 35 seconds at at least 79.4°C. (175°F.), or for at least one second at at least 107.2°C. (225°F.). These regulations are based largely on the premise that paraffination may possess bactericidal properties in addition to waterproofing.

Sanitary Condition and Bacterial Content of Paper Milk Containers.

The significance of this for paper milk containers may be weighed only in relation to the sanitary condition of the glass bottle. The problem for the latter has been discussed above. At a conference on "Sanitation of Paper Milk Containers"¹¹⁰ in July, 1937, several requirements were agreed upon. The first was that only pure virgin mechanical or chemical pulp should be used. This was at no time to harbor more than 500 microorganisms per gram. Nonfermentable adhesives were also specified. Paraffining was to be done under conditions which would not impart flavors or odors to the paraffin or milk. Paraffined containers were to be shipped under conditions which would insure no abuse. Their bacterial content was to be determined by approved methods. In 1936 Rice¹¹¹ examined paper containers from four different manufacturers for their bacterial content by filling with sterile water, incubating at 37°C., for six hours, and then plating. He found a satisfactory condition but believed that bottles made and sealed in the factory were better than those made in the milk-bottling plant.

In a paper read before the Dairy Manufacturers' Conference at the University of Illinois in November, 1937, Prucha reported that examination of over 2,000 paraffined paper milk containers showed that about 50 per cent of them developed no colonies. The remaining 50 per cent developed only a small number of colonies. From a commercial standpoint, the number of bacteria in them was far below the standards suggested for milk bottles. This was confirmed by Rice¹¹¹ and Tanner.¹¹² The latter observed a high percentage of sterile containers and those which were not sterile harbored only a very few bacteria. *Escherichia coli* was not found once in 1,200 containers from each of which five ml. of rinse water were examined. The most recent work on this subject to which the author can refer is that of Rice¹⁰⁹ who examined 1,600 paper milk containers (Pure Pak type) by means of the broth-sterility test and found approximately 80 per cent of them to be sterile. The temperature of the paraffin bath used in the various treatments made practically no difference in the percentage of sterility among the several sets of containers.

Microorganisms in Milk Stored in Paper Containers. Several comparative investigations have been made on the bacterial content of milk stored in various containers. The point of interest here, however, is the relative number of bacteria in milk stored in glass bottles and paper milk containers. This question was studied by some of the earlier investigators.

Allyn¹¹³ found that milk kept at 18.3°C.(65°F.) increased in acidity faster in glass than in paper containers. This observation was confirmed by bacterial counts. Three samples of milk kept at 32.2°C.(90°F.), 21.1°C.(70°F.), and 10°C.(50°F.) showed almost twice as many bacteria in glass bottles as in paper. Paper milk containers are used in foreign countries. Poulsen¹¹⁴ studied a paper container which was sprayed with paraffin internally and externally just before filling. He stored milk in various ways as follows: (1) in paper containers which had been waterproofed with paraffin; (2) in well-washed glass bottles; (3) in glass bottles sterilized with steam; and (4) in chlorine-sterilized glass bottles. Milk stored in the single-service paper milk container was bacteriologically equal to that stored in glass bottles sterilized by steam or chlorine and was vastly superior, bacteriologically, to milk stored in well-washed glass bottles. The paper containers were tight and did not impart a taste to the milk.

Finally, mention may be made of the fact that the Ministry of Health in England, after a thorough investigation, approved a waxed paperboard single-service container for fluid milk. This container made from pure bleached sulfite pulp and waterproofed with paraffin, has been used with satisfaction in England under the name of "Perga" Single Service Milk Container. This container was tested at the National Institute for Research in Dairying¹¹⁵ and found to be satisfactory. The number of bacteria in the cartons was very low and *Escherichia coli* was absent. The bacteriological condition and the keeping quality of milk in the cartons were found to be equal to those of milk in sterile glass bottles. The flavor of milk was not changed. The "Perga" container is in all major details identical with those used in the United States. It is greatly to be hoped that use of such containers may become universal because they meet all salient requirements of a container for fresh fluid milk.

Methods for Testing Milk Bottles and Other Containers for Sterility. The present methods for examination of milk bottles for sterility are the results of many years of study. They are not entirely satisfactory but are probably as satisfactory as present experience and knowledge permit. Having shown that the glass bottle may harbor many bacteria and should be specially treated to make it clean and, perhaps, sterile, the next problem was to secure a method for examining it. Methods developed for research investigations might not be suitable for control laboratories where many bottles have to be examined. Hopkins and Kelly¹¹⁶ placed bacteriological control of bottle sterilization on a par with control of milk. Horn, Rice, and Ramsey¹¹⁷ made numerous tests by plating samples of sterile water used to rinse the bottles, and these results were compared with the counts upon a film of special agar gelatin medium rolled upon the inside of the bottles and incubated for 48 hours. No sufficiently significant differ-

ence was noted between the two methods. The principal factors developed were the dangers inherent in improperly cleansed bottles, the need for better care in cleansing than now obtained, and the tentative adoption of absolute sterility as the proper standard of bacterial content of milk bottles.

Parfitt¹⁰¹ rinsed bottles with 100 ml. of sterile water. The bottle was taken from the line at the filling machine and capped with a sterile cap using sterile forceps. In the laboratory the cap was removed and 100 ml. of sterile water added to the bottle. A new sterile cap was placed on the bottle and the bottle shaken 25 times. Five ml. of the rinse water were added to a sterile Petri dish and nutrient agar added. The count secured after incubation at 37°C. (98.1°F.) for 48 hours was multiplied by 20. Cans were examined in somewhat the same manner. They were rinsed with a volume of water not less than $\frac{1}{20}$ the capacity of the can. The rinse water was plated in the usual manner. Parfitt suggested the agar disc method for examining surfaces of vats, pipe lines, and cans. This has been described in another chapter.

One of the first methods to receive wide acceptance was that proposed by the International Association of Milk Dealers.¹¹⁸ The American Public Health Association¹¹⁹ tentatively approved this procedure. One hundred ml. of sterile water were added to each bottle, capped, and shaken 25 times, making certain to wet the entire interior. One ml. portion of the rinse water was then added to each of two sterile Petri dishes after pouring, and incubated at 37°C. for 48 hours. The number of colonies on each plate multiplied by 100 equals the estimated number of colonies per bottle. Bottles were considered satisfactory when they contained less than one colony per ml. capacity. The American Public Health Association later approved an entirely new technic.¹²⁰ It had been pointed out by Fitzgerald of the American Can Company, that application of the above described procedure to paper milk containers left much to be desired in that such a small amount of rinse water was plated. He suggested in 1937 that 10 ml. be used and the entire amount plated in one large dish (140 mm. x 20 mm.) or distributed in three dishes of the size usually used in laboratories. Consequently Wheaton started to use this method in the laboratories of the American Can Company for examination of paper milk containers.

The eighth edition of *Standard Methods for the Examination of Dairy Products*, 1941, prescribed the use of 20 ml. of sterile tap or buffered distilled water in each bottle. After capping, the bottle is shaken so that all of the interior surface is rinsed. When low numbers of bacteria are expected, 10 ml. of the rinse water are distributed in three sterile Petri dishes. Should large numbers of bacteria be expected, one-ml. portions of the rinse water shall be added to each of two Petri dishes and .1-ml. portion to each of two Petri dishes. Standard agar medium shall then be added to the dishes. After the plates have been incubated at 32°C. (89.6°F.) for 48 hours, the colonies shall be counted. The enumeration of colonies from the plates gives the estimated number of bacteria per

119. Standard Methods of Milk Analysis, Amer. Pub. Health Assoc., Sixth Ed., 1934, 58-59.

120. Idem, Seventh Ed.

bottle. When 10 ml. of rinse water are distributed in three plates, the sum of the colonies on the plates multiplied by two equals the number of bacteria in the bottle; if one-ml. portions were plated in two dishes, the sum of colonies multiplied by 20 equals the number of bacteria in the bottle. Should smaller amounts be plated, appropriate factors must be used. The practice of using smaller quantities of rinse water has been accepted in England by Barkworth⁸⁹ and Mattick and Hoy.⁹⁴ Both of these investigators used 20 ml. of rinse water.

In addition to the methods just mentioned are several others which lend themselves more to research work than routine work. These are patterned after methods which have been used in different fields. They involve introduction of the medium, either melted fluid agar, plain broth, or sterile milk, into the container after which it is incubated in the bottle. These methods do not permit a numerical estimation of the microorganisms but merely indicate the presence of living organisms. When melted agar is added to the bottle, it may be allowed to coat the interior or may harden in the bottom. Incubation of the microorganisms occurs in the container.

A modification of this procedure was used by Mudge and Foard.¹²¹ They introduced 20 ml. of sterile culture fluid, nutrient broth, into the closed container by means of a sterile needle. The container was then shaken and the rinse fluid counted as for glass bottles; or the percentage of sterile containers may be determined after incubation. The results may be reported as percentage of sterile containers.

It is indeed not difficult to summarize the paper milk container situation as far as its microbiological and public-health aspects are concerned. It constitutes one of the great advances in the distribution of safe and clean fluid milk to the public. Microbiologically it is far superior to the washed and sterilized glass bottle, some 80 per cent being sterile, according to Rice,¹⁰⁹ Tanner,¹¹² and others, by the broth-sterility test. Those which are not sterile yield only a few bacteria. The types of bacteria which have been identified have been found to be harmless aerobic spore-formers. Single-service containers are made from clean paperboard which is subjected to processes of heavy chlorination, cooking at high temperatures, and finally, drying on rolls at high temperatures. Each of these is a procedure with pronounced sterilizing value. Waterproofing the container by dipping in hot paraffin wax is the final bactericidal treatment. By and large the paper milk container is far superior to the glass bottle from the standpoint of the consumer, dairyman, and health officer even after the glass bottle has been subjected to the usual washing and sterilizing procedures. The public health aspects have been reviewed by Tanner¹²² and Ball.¹²³

Influence of Age and Temperature on Bacteria in Milk. Time and temperature are very important factors influencing the flora of milk. They cannot be separated. No single extensive investigation has been carried

out on the relation of temperature to development of bacteria in milk. Knowledge has to be pieced together from many different investigations, and in some cases, from data secured with quite diverse organisms.

Luxwolda¹²⁴ found that milk kept at low temperatures developed a large number of bacteria. These did not cause an acid reaction in the milk. At 20°C. (68°F.) lactic acid bacteria appeared and exerted a restraining action on the other forms. This restraining action was steadily diminished as the temperature was lowered. Reed and Reynolds¹²⁵ inoculated sterile flasks of milk with pure cultures and incubated them at four different temperatures for six weeks. As would be expected, the minimum time for maximum numbers of bacteria occurred at the higher temperatures of incubation. Conn and Esten¹²⁶ observed little regularity in the comparative development of different species of bacteria in milk. The number at any time was believed to depend more on temperature than on initial contamination. As to development of bacteria, two periods were recognized: the first in which the number of bacteria was less than 10 million per ml. lasting from 24 to 50 hours, according to whether the temperature was 20°C. (68°F.) or 13°C. (55.4°F.); and the second, in which the number of bacteria was above 10 million, lasting from the end of the first period until time of curdling. Some changes which occurred during the first period were described as follows: The number of bacteria in milk was not increased, but was frequently reduced during the first few hours after milking. At 20°C. most of the species began to increase in absolute numbers after the first six hours. *Bacillus acidi lactici* increased uniformly, the other lactic acid bacteria were irregular in their development, the Streptococcus group always increased, the liquefying bacteria practically always increased in absolute and sometimes in relative numbers, the species of Sarcina developed but little, and the miscellaneous species decreased slightly during the first period. At 13°C. the original period of no growth was increased, the number of bacteria at the end of 50 hours being no greater than that in milk at 20°C. after 18 hours. Rapid development of bacteria after 40 hours was most frequently due to the growth of the Streptococcus group rather than to the lactic acid bacteria. Development of miscellaneous species was favored by the lower temperature. Preliminary icing of milk for a period of 15 hours greatly reduced the number of bacteria, the number present at the time of curdling being much less than in samples not previously iced. Preliminary icing favored development of a number of miscellaneous species, but delayed development of *Bacillus acidi lactici*. Conn and Esten¹²⁶ made another report and gave descriptions of nine groups or types of bacteria and the relative development of these types in market milk at temperatures ranging from 1 to 37°C. Development of different types of bacteria in ordinary market milk was believed to be closely associated with temperature. The initial period, in which no increase in the total number of bacteria occurred was very short when the milk was kept at 37°C. (98.6°F.), but was six to eight

124. Luxwolda. 1911. Centbl. Bakt., Pt. 2, 31, 129-175.

125. Reed and Reynolds. 1916. Virginia Agr. Expt. Sta. Bull. 10.

days when the milk was kept at 1°C.(33.8°F.). Following this period the bacterial content of the milk showed great diversity, depending upon the temperature. It was found that at 20°C.(68°F.) ordinary lactic acid bacteria developed rapidly and at the end of about 40 hours when the milk became curdled, *Bacillus acidi lactici* commonly constituted over 90 per cent of the total number of bacteria. At this temperature, other species were almost completely held in check by the lactic acid bacteria. At 37°C.(98.6°F.) the results were quite different. *Aerobacter aerogenes* commonly predominated over *Bacillus acidi lactici*. *Escherichia coli*, when present, also grew rapidly. At 10°C.(50°F.) all types of bacteria developed somewhat uniformly after the first two or three days, none of the lactic acid types being favored. Neutral bacteria usually grew rapidly and liquefiers often became abundant. This temperature was not so favorable for development of lactic acid bacteria as 20°C.(68°F.). As the growth of other species of bacteria at this temperature was less retarded, the wholesomeness of the milk was more under suspicion. Except as regards the rapidity of bacterial growth, there was but little difference between 10 and 1°C. Conn stated, "Milk is not necessarily wholesome because it is sweet, especially if it has been kept at low temperatures. At the temperature of an ice chest, milk may remain sweet for a long time, and yet contain enormous numbers of bacteria, among which are species more likely to be unwholesome than those that develop at 20°C.(68°F.). From this standpoint the suggestion arises that instances of ice-cream poisoning are perhaps due to the preservation of cream for several days at a low temperature, such treatment keeping the milk sweet, but favoring the development of species of bacteria that are, at higher temperatures, checked by lactic organisms."

Conn referred to an extreme case where the bacteria multiplied five fold in 24 hours, when the temperature was 10°C.(50°F.), and 750 fold in the same time when the temperature was 21.1°C.(70°F.). Milk kept at 35°C.(95°F.) curdled in 18 hours and at 10°C. in 148 hours. As far as the keeping property of the milk was concerned, low temperature was considered of more importance than cleanliness. Savage¹²⁷ also believed that temperature was more important than initial numbers. In milk kept at 35°C.(95°F.), the species developing most rapidly was the undesirable one, *Aerobacter aerogenes*. At a temperature of 21.1°C. this species developed relatively less rapidly in the majority of cases than *Bacillus lactis acidi*, the latter being very desirable in cream and cheese ripening. The bacteria in milk kept at 10°C. increased slowly and later consisted of very few lactic acid organisms but of miscellaneous types, including many forms that render the milk unwholesome. Pennington¹²⁸ found that milk stored at 0°C.(32°F.) underwent marked proteolysis, which was noticeable at the end of two weeks. She stated that proteolysis of casein was due primarily to bacteria, while lactalbumin was destroyed by the enzymes in the milk. The numbers of bacteria greatly increased

127. Savage. 1909-1910. Ann. Rept., Local Govt. Bd., Gt. Brit. 39, 474-503.

128. Pennington. 1908. J. Biol. Chem. 4, 353; 16 (1913), 331-368.

and this increase was most striking in the raw, untreated milk. The freezing-point was gradually lowered with the decomposition. Market milk held below 0°C. increased from 15,956 to 376,000,000 at the end of five weeks. These investigations tend to indicate that milk and other foods may not be held indefinitely even at low temperatures. Changes may eventually take place to render the food unfit for consumption. Pennington continued her investigations to determine which part is due to the enzymes of milk, and, finally, what results when both bacteria and enzymes act together. It was shown that proteolysis of casein is due primarily to bacterial action, while that of lactalbumin is due to the enzymes of the milk. Bacterial and milk enzymes, when active at the same time, cause a greater degree of proteolysis. The fermentation of lactose is largely, if not entirely, due to bacterial action.

Classification of Bacteria Found in Milk. Bacteria in milk are contributed to it by every agent with which it comes in contact. Consequently, attempts to classify the bacteria in milk may not be of great value. Conn *et al.*,¹²⁹ Kruse,¹³⁰ Orla-Jensen,¹³¹ Löhnis,¹³² Beijerinck,¹³³ and Rogers and Davis¹³⁴ are among those who have attempted to do this. Their classifications will not be reviewed here mainly because they are of historic interest now.

Ayers and Johnson's¹³⁵ Milk Tube Method. This is a useful method for grouping bacteria in milk. Five groups of bacteria are recognized depending on the changes induced in tubes of sterile litmus milk. The milk under study is plated in sufficiently high dilution to yield plates with individual colonies. Each colony is transferred to a tube of sterile litmus milk and incubated at 37°C.(98.6°F.) for 14 days. After this incubation period, the cultures fall into the following groups: (1) acid-coagulating, (2) acid-forming, (3) inert, (4) alkali-forming, and (5) peptonizing. This method has the advantage of grouping bacteria according to the changes which they bring about in the milk and not according to some name or charactersitic which may be unimportant as far as milk is concerned.

Alkali-Forming Bacteria in Milk. We are indebted to Ayers *et al.*,¹³⁶ for a study of the alkali-forming bacteria in milk. They are defined as bacteria which produce an alkaline reaction in litmus milk in 14 days, with no indications of peptonization. In the sterile litmus milk tube it appears within five days, sometimes in a shorter period. Ayers believed that the alkalinity was caused principally by the fermentation of citric acid salts to alkali carbonates. Other salts of the organic acids may undergo the same transition if they are present in the milk. Ammonia was found to play little or no role in establishing alkaline reactions. The bacteria which were responsible for these changes grew best aerobically between temperatures of 20°C.(68°F.) and 30°C.(86°F.). The thermal death points of these bacteria in milk were between 60°C.(140°F.) and 65.5°C.(149.4°F.). There was no indication of spore formation but a slimy growth on agar.

Bacteria that possess the property of breaking down protein with the consequent production of an alkaline reaction in milk were thoroughly studied by Storck.¹³⁷ He isolated them from raw milk by plating on China-blue lactose agar and incubation at 30°C. (86°F.). True alkali-forming bacteria were characterized after 48 hours by colonies surrounded by a clear zone easily recognizable under moderate magnification; there was no preliminary blue coloration. The alkali-forming bacteria belonged to the major groups of bacteria which are usually found in milk. These bacteria were considered undesirable in milk especially in the winter time when they might gain ascendancy over the acid formers and cause the milk to clot. Also, some of the alkali formers are able to split fat and cause rancidity in butter. On the other hand, these bacteria might be useful in the soft cheese industry because they could help decompose the casein.

Fat-Splitting Bacteria in Milk. These bacteria have received more attention recently than for many years. Long and Hammer¹³⁸ isolated *Pseudomonas fragi* repeatedly from various dairy products. It is widely distributed and grows well at low temperatures. It frequently grows with a characteristic odor which turns to a rancid odor with time. *Pseudomonas fragi* has never been isolated from pasteurized milk or cream directly from the vat but has been frequently isolated from bottled milk and cream which indicates contamination after pasteurization. Long and Hammer found the species so variable that it was difficult to characterize it. They isolated it from salted and unsalted butter in Iowa. More has been written about these bacteria in other places in this book. They seem to be assuming greater importance in the food industry.

“Fermentation Test” of Milk. This is an attempt to determine the predominant bacterium that is present in milk. The milk is kept in a sterile culture tube at 40°C. (104°F.) for several hours. Normal, clean, fresh milk, according to Van Oijen,¹³⁹ may then turn faintly sour in 12 hours, both in taste and odor, but in most cases will not curdle. If the milk is stored for a longer time, it may curdle and clot without appreciable extrusion of whey. The presence of undesirable bacteria will bring about other changes.

(a) Presence of strongly acid-producing bacteria produces a curd which is not homogenous. The milk curdles and shows large and small flakes.

(b) Gas production may take place, accompanied by a disagreeable odor. Presence of gas-producing bacteria, such as *Escherichia coli* and its relatives, is undesirable.

(c) Curds of different consistencies may be formed. These may be accompanied by bad odors, owing to presence of sporeforming bacteria. Such milk may not be adapted to condensing or dehydration.

STREPTOCOCCI IN MILK

Streptococci are widely distributed in milk and were once thought to be always related to undesirable conditions in the cow's udder which

might cause illness in those who used the milk. Hueppe¹⁴⁰ reported *Bacillus acidi lactici* as the organism causing the souring of milk. In 1894-1895, Günther and Thierfelder¹⁴¹ found another organism differing in characteristics from that described by Hueppe and thought it was the *Bacillus lactici acidi* of Leischmann. Kruse¹⁴² claimed that *Bacillus acidi lactici* (Hueppe) belonged in the *Aerobacter aerogenes* group. He believed that the organism which caused the souring of milk was a streptococcus and, consequently, proposed the name *Streptococcus lacticus*. This name, according to Ayers, was substituted for *Bacillus lactici acidi*. It is well known that Lister was one of the pioneers in the study of the sour-milk bacteria, and proposed the name *Bacterium lactis* for the organism souring milk. Present-day investigators agree that this name should be used, on the grounds of priority. It seems to be replacing other names. After Heinemann¹⁴³ had investigated the bacteria which were said to be concerned with the souring of milk, he believed *Bacillus acidi lactici* to be a myth. The ordinary bacteria producing lactic acid fermentation in milk were said to be *Aerobacter aerogenes* and *Streptococcus lactis*. *Streptococcus lactis* was said to agree in morphological, cultural, and coagulative properties with pathogenic, fecal, and sewage streptococci; it could be demonstrated in cow feces, on the cows, and in the milk. These conclusions are at variance with the work of Ayers of a later date.

Frost and Engelbrecht¹⁴⁴ believe that milk freshly drawn from the bovine udder contains streptococci in a large percentage of the samples. Certain herds may also contain hemolytic streptococci closely resembling, if not identical with, those causing streptococcic sore throat and scarlet fever, but the vast majority of beta-hemolytic streptococci found in milk are either *Streptococcus mastitidis* or the pseudo-hemolytic. Non-hemolytic streptococci were said to be even more numerous than the hemolytic varieties. Frost and Engelbrecht reported that the alpha type of hemolytic streptococci was most common in milk from a number of herds producing certified milk in Wisconsin and northern Illinois as well as herds which were not producing certified milk. Among the strongly beta-hemolytic streptococci of the human type in milk they reported *Streptococcus pyogenes* and *Streptococcus epidemicus*. The former was said to occur typically in man and occasionally in milk. In 12,446 examinations they found it 18 times. They suggested that this organism might be the cause of scarlet fever. *Streptococcus epidemicus* was found 10 times in the same number of examinations. These two strains were said to differ from each other in that *Streptococcus epidemicus* is encapsulated. Frost and his colleague stated that they had found this organism in the certified milk herds during an eight-year period. During the time which they had been under observation, 10 cows were carrying this germ. Frost quoted the work of Edwards, of the Kentucky Agricultural Experiment Station, who

reported a *Streptococcus epidemicus*-like organism in mares. The fermentation reactions, however, of this last strain were a little different from those which had come from streptococcic sore-throat outbreaks.

Streptococcus lactis. This organism, as just indicated, has been known under many different names. Study of the many papers which have been written on it indicates that a group of somewhat related streptococci are concerned. Many of the investigators speak about varieties of *Streptococcus lactis* established usually on the basis of some special property. Hammer and Baker¹⁴⁵ suggested several such species. Identity of species is indeed confused by the fact that fermentation reactions are not stable. This makes possible many fermentation varieties which confuse new investigators. Yawger and Sherman¹⁴⁶ reported cultures of *Streptococcus lactis* which gradually acquired ability to ferment lactose. According to Brown,¹⁴⁷ this organism grows rapidly in milk at fairly low temperatures producing a high acidity and is quite resistant to heat, usually surviving 60°C.(140°F.) for 30 minutes. Ayers, Johnson, and Mudge¹⁴⁸ did not find the organism in the mouths, udders, or feces of cows and believed that it gained entrance to milk from dairy utensils. Some workers have found *Streptococcus lacticus* to be indistinguishable from *Streptococcus faecalis* of the human intestines. It seems, therefore, that streptococci must not be accepted as indigenous to milk.

Considerable study has been given to the problem of the origin of *Streptococcus lactis*. According to the results of investigations by Rogers and Dahlberg,¹⁴⁹ Evans,¹⁵⁰ and Ayers, Johnson, and Mudge¹⁴⁸ *Streptococcus lactis* does not originate normally in the cow's udder.

Esten¹⁵¹ could not find *Streptococcus lactis* in nature. When it was found it was considered to be accidental; however, it was found in the cow's mouth and intestinal tract. Any object which could be reached by the tongue of the cow was, therefore, believed to be a constant source of the organism. Barthel found it ever-present in the stable.

A recent attempt by Stark and Sherman¹⁵² to answer this question seems to indicate that *Streptococcus lactis* lives normally on plants. They isolated 200 strains of *Streptococcus lactis* from various sources, such as fresh corn, navy beans, cabbage, wheat, garden peas, and head lettuce. Cultures from mature corn, aged heads of cabbage, lima beans, alfalfa, soil, and intestines of earth worms proved negative, but the number of samples examined was fairly small. The organism was not found in the mouths and throats of cows nor in bovine or human feces, though *Streptococcus faecalis* was isolated from all these situations. It would appear that certain plants constitute the natural habitat of *Streptococcus lactis* and that this organism finds its way into milk from these sources.

The serological grouping method of Lancefield,¹⁵³ which has proved of value for differentiation of hemolytic streptococci into more or less species-specific groups, was not successfully used by Sherman, Smiley, and Niven¹⁵⁴ for non-hemolytic streptococci except in these groups which included both hemolytic and non-hemolytic varieties, such as groups B and D. In group B (*Streptococcus mastidis* and its varieties) non-hemolytic strains may be serologically identified quite as satisfactorily as those which are hemolytic. In group D (enterococci), also, are found a number of closely related entities, the non-hemolytic *Streptococcus fecalis* and varieties and the hemolytic *Streptococcus zymogenes* and varieties.

Sherman and his colleagues further confirmed the serological identity of *Streptococcus lactis* by producing "species-specific grouping sera" for this organism. Variants may occur as shown by Sherman and Yawger.¹⁵⁵ Four cultures of an organism which did not ferment lactose but identical in all other respects with *Streptococcus lactis*, were isolated. One strain acquired the ability to ferment lactose after several months.

Identity of *Streptococcus lactis* (*Streptococcus lacticus*) and *Streptococcus pyogenes*. *Streptococcus pyogenes* of Rosenbach is a Gram-positive coccus, causing infection of man. It is very much like *Streptococcus lactis*—in fact, so much so that Heinemann,¹⁵⁶ after a comparative study, believed that they were identical. This was a most interesting statement in view of the position which *Streptococcus pyogenes* has as a pathogen for man. In the second paper, Heinemann¹⁵⁷ reported the results of an attempt to determine whether the virulence of *Streptococcus lactis* might be increased by successive passages through animals. Five strains of *Streptococcus lactis*, from different sources, and three of *Streptococcus pyogenes* were used. The conclusion was reached from the investigations that these two organisms are closely related, not only in morphological and cultural characters, but in pathogenic properties. The virulence of *Streptococcus lactis* was gradually increased by repeated passages through rabbits, so that after five or more passages, two ml. of a 24-hour-old broth culture were fatal in subcutaneous injections. The same amount injected intravenously was fatal to the first animal. The lesions of *Streptococcus lactis* in rabbits were the same as those produced by *Streptococcus pyogenes* in man. Ruediger,¹⁵⁸ however, reported that *Streptococcus pyogenes* could be separated from *Streptococcus lactis* by means of blood agar plates. The latter were said to produce small colonies surrounded by a large zone of hemolysis, whereas the former produced green or greenish colonies with little or no hemolysis. *Streptococcus pyogenes* was said to occur rarely in milk, and when it does occur, it indicates an inflamed condition of the udder. This latter opinion seems to be confirmed by the work of Baehr.¹⁵⁹ He found *Streptococcus pyogenes* in only two samples of milk examined;

one of them came from a cow with a diseased udder. On the other hand, *Streptococcus lactis*, as described by Kruse,¹⁶⁰ was present in a large percentage of samples.

Significant differences between these two organisms were also reported by Saito¹⁶¹ and Sherman and Albus.¹⁶² They reported differences in chain formation, ability to coagulate milk, and fermentation reactions, and especially a marked difference in ability to reduce stains. *Streptococcus lactis* reduced methylene blue, litmus, and indigo carmine very promptly, while the pyogenes group had no effect on the first named and decolorized the others very slowly and incompletely, and only after curdling had taken place. It was also observed that all the cultures of lactic acid bacteria grew at 10°C.(50°F.), while none of the other group developed at this temperature. Sherman and Albus believed that the two groups could be distinguished. Those who desire a comprehensive survey of the streptococci should consult the publication by Thomson and Thomson,¹⁶³ and the more recent publications of Sherman¹⁶⁴ and his colleagues. Kleckner¹⁶⁵ used more refined methods in trying to compare these two types of streptococci. He isolated 50 strains of each and made detailed studies on the growth and action in various media. Finally, immune sera were prepared and agglutination, cross-agglutination, and agglutinin absorption tests made. They showed no real difference between these two types of streptococci. Slight variations which occur are not of real importance since they may occur not only between two types but also among the members of the groups themselves. These slight variations perhaps are due to the fact that the organisms undergo changes according to environmental conditions. Since the lactic acid streptococci appear to be able to withstand conditions as they occur in the animal body, it is reasonable to assume that they should be found in the intestinal tract. As indicated here and also by other workers, there seems to exist no real difference between the fecal streptococci and those normally found in milk. Therefore, it is felt that the *Streptococcus lactis* ingested with milk and some milk products, is of the same type as that found in the feces. From here they may enter the soil where only the most vigorous can survive and in turn enter milk through sources of contamination. In a study of the transformation of *Streptococcus fecalis* Starck¹⁶⁶ considered the following to be the critical differences between the two "forms": *Streptococcus fecalis*—heat resistant [30 min. at 63°C.(145.4°F.) in milk], late fermentation of pentoses (arabinose and rhamnose); *Streptococcus lactis*—non-heat-resistant, early fermentation of litmus milk not able to ferment pentoses.

A change of character from *lactis* to *fecalis* could be brought about by successive passages in certain media, e.g., milk, peptone milk, brewer's mash, mash with peptone, decoction of rye, etc., particularly with the last

two media. To all these media it is necessary to add chalk. The change could also be brought about by passage through mash medium to which various digestive enzymes and bile has been added. This suggests that the transformation may take place in the alimentary canal and that some of the streptococci in the feces with the characters of *Streptococcus fecalis* are derived from *Streptococcus lactis* introduced with the food in the milk. According to Sherman, Mauer, and Stark¹⁶⁷ the *Streptococcus fecalis* group is a homogeneous one. They found no reason for subdividing it on the basis of results from fermentation tests.

These organisms were not considered to be identical by the committee which prepared the fifth edition of Bergey's *Manual of Determinative Bacteriology*. Both are listed as distinct species.

Streptococcus cremoris. This streptococcus was described in 1919 by Orla-Jensen.¹⁶⁸ It had probably been confused with *Streptococcus lactis*. Its normal habitat seems to be dairy products. Sherman¹⁶⁴ stated it does not grow as well in artificial media as does *Streptococcus lactis*. Yawger and Sherman¹⁴⁶ studied the physiological characteristics of 41 cultures of lactic acid-producing streptococci identified as *Streptococcus cremoris* and 25 cultures identified as *Streptococcus lactis* by methods described and gave definite evidence that these species can be clearly differentiated and that *Streptococcus cremoris* is entitled to rank as a separate species. An extensive description of this organism was presented. *Streptococcus cremoris* can be separated from *Streptococcus lactis* by the inability of the former to produce ammonia in four per cent peptone and by its inability to grow at 40°C. (104°F.) in the presence of four per cent sodium chloride and in broth at pH 9.2. It is also generally less tolerant to methylene blue than *Streptococcus lactis*. In a later publication Sherman, Smiley, and Niven¹⁵⁴ reported that *Streptococcus cremoris* seemed to be closely related serologically to *Streptococcus lactis*. Whether or not these two "lactic" organisms belong to the same serological group is not clear on the basis of our limited data. Most strains of *Streptococcus cremoris* react weakly with anti-lactis group sera. Some attempts to produce anti-cremoris group sera have failed. This finding of an apparently close serological relationship between *Streptococcus lactis* and *Streptococcus cremoris* appears to agree with results reported by others. Apparently pure strains of this organism may not be permanent, for Hunter¹⁶⁹ observed well marked variation in pure strains, especially in acid production and certain other characteristics. Klingmuller¹⁷⁰ could not distinguish between *Streptococcus mastitidis* and *Streptococcus cremoris*.

According to Ayers and Johnson,¹⁷¹ the typical udder streptococcus of the cow is *Streptococcus mastitidis*. This streptococcus was said to be practically identical with *Streptococcus pyogenes*, when the ordinary cultural characters are considered. However, they can be separated by their

ability to split sodium hippurate. According to the same investigators, the characteristic streptococcus of cow feces is *Streptococcus bovis*. This streptococcus does not produce gas from dextrose, and is thus differentiated from *Streptococcus kefir*, which does form gas from dextrose and which ferments raffinose. Hammer¹⁷² reported *Streptococcus paracitrovorus* as commonly present in milk. Ayers believed that this organism should be placed in the *Streptococcus kefir* group. Ayers, Johnson, and Mudge¹⁴⁸ stated that *Streptococcus kefir* predominated in milk with low acidity and *Streptococcus lactis* in milk with high acidity. Ayers,¹⁷³ before the World's Dairy Congress, summarized the results of his work in this field and reported a new species in the udder to which he gave the name *Streptococcus acidominimus*. He further reported that there was no reason for assuming that *Streptococcus mastitidis* was pathogenic for man and that it could be readily differentiated from human hemolytic streptococci.

Streptococcus liquefaciens. The 101 cultures which were isolated from dairy products by Long and Hammer¹⁷⁴ varied widely in their production of volatile acid, carbon dioxide, and acetylmethylcarbinol in skim milk. Diacetyl was not produced by any culture. Volatile acid production was not correlated with the fermentation of sucrose or the rapidity of reduction of litmus milk. The production of carbon dioxide and acetylmethylcarbinol did not vary directly with the volatile acid produced. Smaller amounts of these substances were formed at 37°C. (98.6°F.) than at 21°C. (69.8°F.). The addition of .2 to .4 per cent citric acid to skim milk generally reduced volatile acid production.

HEMOLYTIC STREPTOCOCCI IN MILK

Practically all investigations which have been made on the subject indicate that nearly all raw market milk may contain hemolytic streptococci, even of human origin, which is another strong argument for universal pasteurization. Gunnison *et al.*¹⁷⁵ found such streptococci in 134 specimens of raw market milk from as many different dairy farms. Most of these strains produced double zones of hemolysis in rabbit-blood agar. Their work confirmed conclusions which had been reached by other investigators in the same field. Sherman and Niven¹⁷⁶ examined a total of 313 samples of commercial milk, 68 raw and 245 pasteurized, for hemolytic streptococci. Narrow-zone hemolytic types in blood agar, the most typical form of *Streptococcus mastitidis* were not considered. Only 8.5 per cent of the pasteurized samples contained hemolytic streptococci, whereas broad-zone hemolytic types were obtained from 18 per cent of the raw samples. The cultures isolated were studied serologically and physiologically and, on the basis of these results, six groups or species were recognized: *Streptococcus mastitidis* (Lancefield group B), the "animal pyogenes" (Lancefield group C), *Streptococcus durans* (Lancefield group D), and two other types which differ serologically and physiologically from any adequately

described species of *Streptococcus*. The prevailing types of hemolytic streptococci in raw milk are *Streptococcus mastitidis* and the "animal pyogenes"; the most common forms in pasteurized milk are *Streptococcus durans* and *Streptococcus zymogenes*. While it is known that intramammary contamination is often gross Pullinger and Kemp¹⁷⁷ assumed that contamination by a human being is more likely to be slight or intermittent. They contaminated different grades of raw and heated milk with *Streptococcus pyogenes* and then stored the milk at various temperatures. These organisms multiplied readily in sterilized milk but in fresh raw milk they multiplied slowly only after from 48 to 72 hours. Similar results were secured in laboratory pasteurized milk. In all cases the organisms multiplied slowly at 15°C.(59°F.). Commercially pasteurized milk and raw graded milk bottled for distribution were said to sour too rapidly for multiplication of *Streptococcus pyogenes* following artificial contamination.

Streptococcus thermophilus. Sherman and Wing¹⁷⁸ described this organism as a new species. It differs from the pathogenic hemolytic streptococci in its higher maximum temperature for growth and a higher heat resistance. It differs from the types of human origin by hydrolysis of sodium hippurate and failure to ferment sucrose.

Streptococcus epidemicus. This is a pathogenic species first described by Davis¹⁷⁹ as the etiologic agent of septic sore throat. The fifth edition of Bergey's *Manual of Determinative Bacteriology*, published in 1939, considers this organism to be identical with *Streptococcus pyogenes*.

Streptococcus agalactiae. This is the name now applied to the *Streptococcus* causing bovine mastitis. Formerly the organism was called *Streptococcus mastitidis*. The literature on bovine mastitis is voluminous. Those who wish a good review of the more important contributions should consult Sherman's¹⁶⁴ review and Hansen's^{179a} discussion of the identity of this species. Minett and Stableforth¹⁸⁰ believed that in addition to *Streptococcus agalactiae*, the organism of bovine mastitis, and *Streptococcus pyogenes* type, some of which may be responsible for human sore-throat outbreaks, other beta-hemolytic streptococci may be found in milk. Such streptococci are not as a rule numerous and may be found in the milk from individual cows. Of 150 individual cows from four herds whose mixed milk contained such streptococci they were cultivated from 29 quarters of 21 cows, but usually in quite small numbers. Samples from about 300 cows belonging to eight other herds failed to show these streptococci. They form two groups called here "low-acid" strains and *Streptococcus infrequens*. Their characters are described in detail. Although highly hemolytic they were nonpathogenic for laboratory animals and gave no results when introduced into the cows udder. The two groups could be distinguished from *Streptococcus agalactiae* and *Streptococcus pyogenes* by direct agglutination and the two groups from each other by agglutinin absorption methods.

Pathogenic bacteria are influenced in milk as are other bacteria. Pullinger and Kemp¹⁷⁷ grew three strains of *Streptococcus pyogenes* in sterilized milk; considerable multiplication took place at 22°C. (71.6°F.) and 18°C. (64.4°F.) and also at 15°C. (59°F.), but at a much slower rate. With laboratory pasteurized milk, multiplication began only after 48 to 78 hours of storage at 18 to 22°C. (64.4 to 71.6°F.). With commercial pasteurized milk at 18°C. they diminished up to 48 hours, at 22°C. the milk soured within 48 hours but showed no tendency to streptococci multiplication.

In fresh raw milk the usual result was a diminution of *Streptococcus pyogenes*, and only multiplication, and that comparatively slowly, after 48 to 72 hours of storage at 18 to 22°C. The different strains used showed some differences in this respect, the newly isolated strain showing least multiplication. There was also no multiplication at 15°C. These are significant findings since they suggest that with chance contamination of milk from an infectious case or carrier there is no likelihood of rapid multiplication and a serious milk spread outbreak. It is suggested that infected cows play a major part in the spread of milk-borne *Streptococcus pyogenes* epidemics.

Procedures for Determining Hemolytic Streptococci in Certified Milk.¹⁸¹ "Deep colonies in blood agar plates are necessary for the recognition and differentiation of streptococci. The surface inoculation of blood agar plates is not satisfactory. Blood agar plates poured as here recommended may also serve for determining the total bacterial count of milk and in fact, for Certified Milk, blood agar is sometimes a more suitable medium for this purpose than the agar recommended in Section 1 of the Appendix since Certified Milk is relatively free from all bacteria other than those which come from the udder and many of these grow best in blood agar. If blood agar is to be used for making total counts, use only 5% of blood in the agar.

"Samples of milk should be diluted 1:10 and 1:100 in sterile salt solution (0.85% NaCl). One ml. amounts of these dilutions shall be pipetted into sterile petri dishes. To the melted agar cooled to between 45° and 50°C., add 5% to 10% of sterile defibrinated horse or rabbit blood; less is known about the appearances when beef blood is used. The blood is immediately well mixed with the agar and 10 to 12 ml. are poured into the petri dishes containing the milk. The petri dishes shall be rocked immediately to insure uniform mixing of the milk with the medium. When the agar has solidified the plates shall be incubated in an inverted position at 37°C. The petri dishes shall be 9½ to 10 cm. in diameter and shall have glass tops; porous tops may not be used. The plates should be examined after incubation overnight and again after incubation for another day. Beta hemolytic streptococci, produce about the deep colonies clear colorless zones of hemolysis. When studied under the low power of the microscope beta zones of hemolysis should show no blood corpuscles remaining next to the deep colony. In the examination of blood agar plates it cannot be assumed that all colonies with beta zones are streptococci since certain strains of staphylococci, colon bacilli, and other organisms may also be hemolytic. Gram stained smears from the colonies or from subcultures from the colonies must be examined. For the identification of hemolytic streptococci two methods are available, the cultural method and the serological method.

"**CULTURAL METHOD.** For strongly presumptive diagnosis: (1) from the blood agar plates fish deep beta hemolytic colonies; (2) inoculate from the same colony or from a broth culture of the colony into (a) 1% dextrose broth, (b) sorbitol broth and (c) hippurate broth. Strains which are sorbitol-negative, hippurate-negative and which

181. By permission of the American Association Medical Milk Commissions, Inc., Methods and Standards for Production of Certified Milk, New York, N. Y., 1940, p. 18.

attain a pH not lower than 4.8 in dextrose broth after incubation for 48 hours are to be suspected of being human pathogens (usually serological Group A, occasionally Group C). Such strains shall be sent promptly to the nearest Regional Laboratory of the A.A.M.M.C. for further study and, if possible, should also be studied by the local Commission Laboratory. Instructions as to details and for further study may be obtained from the Committee on Methods and Standards of the A.A.M.M.C. The hemolytic mastitis streptococci of serological Group B are sorbitol-negative and hippurate-positive. There are also many non-hemolytic mastitis streptococci. The so-called animal strains of hemolytic streptococci of serological Group C, less frequently a cause of mastitis, are sorbitol-positive and hippurate-negative, as are also those of Group E by the usual methods of testing. Hemolytic streptococci of serological Group D attain a final acidity of pH 4.0 to 4.5 in dextrose broth, are variable in their sorbitol and hippurate reactions, and are resistant to the temperature of pasteurization.

"SEROLOGICAL METHOD. When suitable Group-specific immune sera are available hemolytic streptococci may be rapidly identified by the precipitin method of Lancefield. A simplified technique makes possible the identification of the serological Group within 24 hours after the colonies are fished from the blood agar plate, and with a minimum of expense and labor. A description of the technique may be obtained from the Committee on Methods and Standards of the A.A.M.M.C. Since cultural study is necessary for the identification of species within the Groups, strains of streptococci found to belong to Groups A or C shall be sent to the nearest Regional Laboratory of the A.A.M.M.C. for further study.

"So far as is known only Group A hemolytic streptococci have caused milk-borne epidemics of septic sore throat or scarlet fever. If any cow should be found to harbor Group A hemolytic streptococci she shall be immediately and permanently removed from the herd. The milk from cows harboring Group C streptococci shall not be used in Certified Milk production, and such animals shall be segregated from the milking herd. Cows harboring streptococci of Group B shall be regarded as carriers of mastitis streptococci and potential sources of infection for other animals in the herd.

"Where facilities permit it is recommended that at least once a month samples of milk should be taken from groups of about 10 cows; that these samples should be diluted 1:20 with sterile salt solution (0.85% NaCl), plated in blood agar and studied for hemolytic streptococci. In case the presence of streptococci pathogenic for man is suspected in any of the group samples, milk from the individual cows of this group should be cultured and any cow found to harbor the organisms should be permanently removed from the herd. This same procedure is to be adopted if at any time there is any reason to suspect that pathogenic streptococci may have gained entrance to the milk supply or that any cases of milk-borne streptococcal disease have appeared among consumers of the milk, or that there may be present in the herd cows shedding large numbers of bacteria in their milk.

"Swabs from throats shall be sent promptly to the laboratory and there cultured by either of the following methods: (1) Place the swab into a test tube of about 5 ml. of broth and shake off the bacteria. One small loop of the broth suspension inoculated into a 10 or 12 ml. tube of melted blood agar prepared as described above, usually makes a proper dilution for a good plate which should contain not more than 100 to 200 colonies of all kinds. (2) Streak the swab across one edge of the solidified surface of a nutrient agar plate (preferably infusion agar without blood or dextrose, as described above). With the wire loop streak the material from the original streak over the remaining surface of the agar. Over the inoculated surface pour not more than 5 ml. of melted blood agar prepared as described above. After incubation of the plates deep colonies with beta zones of hemolysis are to be fished and the streptococci identified as described above."

Filterable or Virus Forms in Milk. On several occasions investigators have proposed the existence of filterable or virus forms of bacteria in milk and milk products. By dilution and plating methods, they estimated

the numbers of these forms to vary from 10 million to a trillion per milliliter in raw milk, fermented milk, ice cream, cheese, and butter. Sherman and his colleagues¹⁸² suggested that these forms might represent a cyclo-stage in the life history of ordinary bacteria. They relate no practical significance to these forms. Mudge¹⁸³ thought along the same line where he proposed in milk the existence of dormant "invisible spores" of thermophilic bacteria. Mudge believed that milk has a large number of organisms which are not demonstrable by ordinary means. The phenomenon is also involved in a cycle of growth forms in some of which the organism is easy to destroy; in others it is difficult to destroy. Mudge boiled milk showing no visible evidence of these spores for two hours and after such boiling found them in high dilutions. Boiling had no effect on the vegetation of the spores. Black and Brueckner¹⁸⁴ also reported evidence on this question.

Thermophilic Bacteria in Milk. During recent years thermophilic bacteria have assumed new significance in milk. Early bacteriologists observed these organisms in milk, but attached no significance to them. The earlier literature of this subject has been reviewed by Tanner and Harding¹⁸⁵ and Robertson.¹⁸⁶ Thermophilic bacteria are important in dairy bacteriology because they grow in pasteurizers and raise the counts of pasteurized milk as well as cause off-odors and off-flavors. These forms have been reported in milk by Gorini,¹⁸⁷ Weber,¹⁸⁸ Rabinowitsch,¹⁸⁹ Sames,¹⁹⁰ Morrison and Tanner,¹⁹¹ Dotterer,¹⁹² Yates and Glover,¹⁹³ Hungerford and Harding,¹⁹⁴ and many others whose work will be referred to below.

Thermophilic bacteria are known to exist widely in soil, water, dust, etc. It is easy to understand how they would get into milk. It is well established that they are not in milk as it comes from the udder, as shown by the work of Tanner and Harding¹⁸⁵ and Hansen.¹⁹⁵ Thermophilic bacteria are probably present in all milk, although some samples may have to be incubated at 55°C. (131°F.) to prove their presence. Ayers and Johnson¹⁹⁶ described a species to which they gave the name *Lactobacillus thermophilus*.

Tanner and Harding¹⁸⁵ reported thermophilic bacteria, though not numerous, in all samples of milk obtained after the milk had left the barn. Thermophilic bacteria are widely distributed in milk supplies of this country, as samples of milk, milk plates, and cultures, obtained from New York, Michigan, Illinois, Kansas, Missouri, and California, have been

found to contain them. A study of 73 cultures of thermophilic bacteria, isolated from milk, showed that all were motile, Gram-positive, sporeforming rods, which grew well at pasteurizing temperatures. Several were strict thermophiles, not growing at 37°C. (98.6°F.), while others were facultative thermophiles growing at 37°C., and some grew even as low as 20°C. (68°F.). Most of the cultures were facultative anaerobes, but many were strict aerobes; most of the cultures digested starch, produced acid and no gas from dextrose and saccharose, and produced no acid from lactose. The action in milk, although slow, led, in many cases, after many days to the production of a rennin curd and slight alkalinity. Many of the cultures seemed to be inert in their action on litmus milk. Thermal death-point determinations, made with a modified Bigelow and Esty technic, showed wide variations in heat resistance of spores formed at 55°C. (131°F.) on plain agar, suspended in neutral saline, and heated at 100 to 103°C. (212 to 217.4°F.). One strict thermophile formed spores which withstood boiling temperature for over six hours. Data were presented which show that thermophilic bacteria may be one of the causes of the appearance of pinpoint colonies on plates from pasteurized milk. This is due either to the effect of temperature on the growth of these forms or to the inherent tendency to form punctiform colonies on agar, even after long incubation time.

Yale and Breed¹⁹⁷ mentioned several factors which had been found to favor the development of thermophilic bacteria in milk: 1, presence of these organisms in the raw supply; 2, repasteurization of milk returned from milk routes; 3, prolonged holding at pasteurization temperatures; 4, cooking of milk solids on the walls of internal tube heaters and regenerative heater-coolers; 5, dead ends in pasteurization equipment; 6, filter cloths; and 7, development of thermophiles in the pasteurizer itself. Yale found faulty plant operation to be more important in development of thermophiles than the type of pasteurizing equipment. Eckford¹⁹⁸ found that thermophiles from milk and milk products were divided into two groups, *i.e.*, *obligate thermophiles*, which developed from 42°C. (107.6°F.) to 63°C. (145.4°F.) or 75°C. (167°F.), with an optimum between 50°C. (122°F.) and 60°C. (140°F.), and *thermotolerant* organisms, which developed from 35°C. (95°F.) to 70°C. (158°F.) and 75°C. (167°F.), with an optimum between 50°C. (122°F.) and 60°C. (140°F.). Their cultural and other characteristics were described. Both groups had little or no proteolytic ability, and their fermentative activities were slight or absent. They had little or no effect as regards damage to milk or other foods. A thermophilic streptothrix was, however, isolated which was proteolytic, and may be of significance in the ripening of cheese. Distinction should probably be made between thermophilic and thermotolerant bacteria. The former grow best at higher temperatures while the latter are merely heat resistant. Both groups survived pasteurization and even 100 to 120°C. (212 to 248°F.) for 15 minutes. The obligate thermophiles were found to

197. Yale and Breed. 1930. Amer. J. Pub. Health 20, 1192-1198.

multiply in milk from 42 to 63°C. (107.6 to 145.4°F.), but the thermotolerant strains multiplied greatly at this high temperature and particularly at 55°C. (131°F.). They, therefore, may cause trouble in pasteurization plants by multiplying during the process and giving the milk a high count. They may cause pin-point colonies in plates from pasteurized milk at 37°C. (98.6°F.). They were not found by this author in canned milk, sweetened or unsweetened.

Robertson,¹⁸⁶ Clark and Dougherty,¹⁹⁹ Prickett and Breed,²⁰⁰ and Prickett²⁰¹ have contributed to the subject. Prickett's report contains descriptions of species. Thermophilic bacteria are quite as important in other foods as in milk.

Mudge and Thorwaldson²⁰² stimulated thought in this field by claiming that thermophilic bacteria in milk may exist as invisible spores. These germinate and account for the large numbers of cells which are demonstrated to be present by plate counts. Work in other fields on filterable forms seems to lend support to Mudge's opinions.

Methylene Blue Reductase Test for Determining Thermophilic Bacteria in Milk. The use of the methylene blue reductase test for determining the relative number of bacteria in milk has been discussed in another paragraph in this chapter. Harding and Ward²⁰³ stated that this test could also be used for determining the presence of thermophilic bacteria in pasteurized and raw milk. These investigators recommended incubation at 62.5°C. (145°F.). While they do not give the exact technique for carrying out the test, one may assume that it is like that used with the organisms growing about 37.5°C. (99°F.).

Thermophilic bacteria can be controlled by proper plant practices and by avoiding longer than necessary heating of milk. Hansen²⁰⁴ stated that a bacteriological study of a dairy plant by means of the Breed microscope method or by plating usually revealed the source of these bacteria. Thomas²⁰⁵ also related presence of thermophilic bacteria in milk to unsanitary practices in the dairy. He found that plating on milk agar was the best method of enumerating them. They were present in most of the samples of raw milk produced under unsatisfactory conditions but in only three per cent of the clean raw samples. According to Gerhardt²⁰⁶ elimination of dust is important in control of thermophilic bacteria in a dairy.

With one exception none who have worked with the thermophilic bacteria has ever reported that they might be pathogenic. Hansen²⁰⁷ grew the following thermophilic sporeforming bacteria in milk and fed some of the cultures to guinea pigs: *Bacillus aerothermophilus* Weinzierl, *Bacillus calidus* Blau, *Bacillus coagulans* Hammer, *Bacillus kaustophilus* Prickett, *Bacillus michaelisii* Prickett, *Bacillus nondiastaticus* Bergey, *Bacillus thermoliquefaciens* Bergey, a strain of Cameron and Esty's group 80, and a

strain of their group 100. The animals increased normally in weight during and after the feeding experiment. None of the species tested produced detectable toxic substances. Feeding experiments with obligate and facultative thermophilic bacteria yielded only negative results with rabbits and guinea pigs.

Pin-Point Colonies on Agar Plates Made from Milk. These are minute colonies which appear on agar plates made from milk. Some of them are quite visible with the naked eye while others are visible only with the help of a lens. After they were recognized on agar plates, milk-control officials wondered whether they should be counted. If they were counted, many milk supplies would not pass requirements in cities where plate-count standards had been adopted. It was argued by some that they were of no sanitary significance and should, therefore, be ignored. This was a doubtful position to assume, for differences of opinion might occur as to what a "pin-point" colony is. They were first recognized as of importance on plates made from pasteurized milk and were related accordingly to the pasteurization process. Such a relationship is not necessary, for some pin-point colonies occur on agar plates seeded with other foods. Various explanations for their appearance are possible and have been made. These involve the organism itself as well as the conditions which exist on the plate. While some types of bacteria causing such colonies are thermophilic, it is known that mesophilic bacteria may also cause them. Diehm²⁰⁸ suggested the term "minimo-visible" as more suitable than "pin-point" for those colonies which appear so small that they are just visible with a hand lens. The cultures which Diehm isolated were heat-resistant, but not thermophilic, since they would not grow at 60°C. (140°F.). Most of them were *Streptococcus lactis* varieties. Prickett and Breed²⁰⁰ stated that the "pin-point" problem was a complex one, due to the variety of heat-resistant and thermophilic bacteria which may survive pasteurization. Many of these types may cause pin-point colonies on agar plates. These investigators believed that heat-resistant and thermophilic bacteria may be controlled, partially at least, by careful observance of the rules of cleanliness and certain corrective measures about the dairy.

Fay²⁰⁹ explained "pin-point" colonies as due to thermotolerant organisms. In making counts of ice cream on standard plain agar large numbers of "pin-point" colonies on the low dilution plates (1-100) were noted, but not in proportionate numbers or none in higher dilutions (1-1,000). Replating of samples on saccharose agar revealed the "pin-point" colonies in all dilutions and in proportionate numbers. Furthermore, replating on plain agar, containing in the higher dilution plates .001 ml. of sterilized ice cream, which supplied the same amount of sugar as was present in the lower dilution, resulted in the growth of the "pin-point" colonies in all dilutions. With a few exceptions, all pure cultures isolated from these "pin-point" colonies would withstand three or more pasteurizations at 62.18°C. (145°F.) for 30 minutes without decrease in number. All cultures

208. Diehm. 1927. N. Y. Prod. Rev. and Amer. Creamery 65, 338-341.

209. Fay. 1927. J. Bact. 13, 347.

were thermotolerant, but not highly thermophilic, since none grew above 45°C.(113°F.). Fay confirmed his earlier work and conclusions of other investigators, that these bacteria survive pasteurization temperatures but do not grow within this temperature range. He isolated and studied the characteristics of a number of individual bacteria of this thermotolerant group. They all failed to develop at temperatures above 47°C.(116.6°F.). It was noted that these strains develop, when plain agar plates are made from milk, only on low-dilution plates (*e.g.*, 1:100) and not in high dilutions. This is probably related to the fact that the addition of very small amounts of carbohydrate greatly facilitates their appearance on plates, the small amount of lactose carried over in a 1:100 milk dilution adding sufficient sugar. All the strains isolated were nonsporing organisms of various types. The survival of sporing forms which are heat-tolerant represents another phase of the problem not studied in this paper. On the practical side, Fay rejected compounding of media which would eliminate them, but preferred to look upon them as undesirable organisms, indicating improper care of the milk, and the aim should be their elimination by preventive measures. Swenarton²¹⁰ believed that "pin-point" colonies appeared with greatest frequency in the early spring. This was true for standard raw, standard pasteurized, and selected raw milk. Fifty of the 52 cultures isolated from typical plates were found to be streptococci. Since Swenarton probably picked these colonies from plates which had been incubated at 37°C.(98.6°F.) and not at 55°C.(131°F.), it is quite possible that he would not encounter thermophilic bacteria. Swenarton's organisms may not have been thermophilic.

Ayers and Johnson's²¹¹ *Lactobacillus thermophilus* has been found to produce pin-point colonies under certain conditions. They found the organism to be the cause of pin-point colonies on plates made from the milk of one plant. Charlton²¹² reported the same organism causing them in another plant.

Phelps²¹³ made a general survey of the pin-point colony findings in the routine milk samples from 82 dealers for about two and one-half years. The presence of pin-point colonies was not seasonal; no one type of organism was responsible for pin-point colony character after isolation and subculture. Pin-point colonies were found oftener in raw milk, suggesting that the true source of these organisms is ordinarily the raw milk. The appearance of pin points on laboratory plates often coincided with finding by the milk inspectors of either improper plant practices or a bad raw milk supply. Walts²¹⁴ found thermophilic bacteria to be often responsible for these colonies.

Utensils may be one source of bacteria which cause sporadic appearance of pin-point colonies. Robinson²¹⁵ traced one such instance to the can washer.

Sporeforming Bacteria in Milk. Since these bacteria are not found in the cow's udder, they should probably not be present in milk which is being carefully handled. When they are present it means that dust has fallen into the milk or that it has even received more objectionable contamination, such as cow manure. Most sporeforming bacteria in milk are anaerobes and consequently bacteriological procedures are pointed at them more than aerobes.

Bacteriological methods devised for the control of milk supplies have involved aerobic bacteria almost entirely. A few attempts have been made to correlate the anaerobic bacteria content of milk with the conditions under which the milk was produced. Savage²¹⁶ found quite satisfactory agreement between the number of spores of *Clostridium sporogenes* and *Escherichia coli* in over 50 samples of fresh milk. A number of anaerobes including *Alcaligenes fecalis*, *Clostridium welchii*, *Bacillus ephemeros*, *Bacillus pseudotetani* and several unidentified species were isolated by Brown.²¹⁷ Hewlett and Barton,²¹⁸ however, found no correlation between low-grade milk and its content of total bacteria, *Escherichia coli* and *Clostridium sporogenes*.

The investigations of Barthel²¹⁹ led him to conclude that obligate anaerobic bacteria occurred but very rarely in common market milk. Those that were found were almost wholly of two species, Schattenfroh and Grassberger's nonmotile butyric acid bacterium and *Clostridium putrificum*. During the fall and winter months, the former occurred much more frequently than the latter, while the opposite was true during the spring and early summer. Obligate anaerobes were considerably more numerous during the summer months than in the fall or winter, as are also the total bacteria of the milk. No direct relation was found between the general hygienic condition of milk and appearance therein of obligate anaerobic bacteria. Barthel furthermore concluded that *Clostridium putrificum* and *Paraplectrum foetidum* (Weigmann) were identical. From examination of over 50 samples of market milk collected in Washington, Pryor²²⁰ was able to confirm Flügge's original observation as to the presence of spore-bearing bacteria. In his experience the most important species was *Clostridium welchii*, which was believed to be universally present. Aerobic spore-bearing bacteria belonging in general to a group of gelatin liquefiers were also found. Such species did not develop normally in raw milk, nor in milk sold in Washington as "pasteurized," only the ordinary lactic acid bacteria being found. All these spore-bearing organisms had a profound effect upon milk, and when their development was not hindered by lactic acid bacteria, produced changes of decomposition and putrefaction which rendered milk unfit for food. How far they play a role in clinical conditions, especially in children, remains to be proved. Ford²²¹ has shown that the anaerobes in heated milk, which

bring about stormy fermentation, form poisons which cause death when inoculated into guinea pigs. Experiments with *Clostridium welchii* yielded the same results. The maximum toxicity, although variable, seemed to be reached in 24 hours.

While spores of anaerobic bacteria are not common in milk, Hussong and Hammer²²² described several abnormal conditions in dairy products caused by anaerobic bacteria. Several involved the appearance of gas in milk and one rancidity in pasteurized cream.

Standard methods of milk analysis do not provide for examination of milk for anaerobic bacteria. Several attempts have been made, however, to show that they may have sanitary significance.

Savage's Anaerobic Spore Test as an Indication of Contamination of Milk. The anaerobic spore-bearing bacteria have been associated with sewage pollution and contamination. British sanitarians have used the test especially in water analysis from which it was quickly adapted to other fields of work. While there are quite a number of anaerobes and the group is not clearly understood, the name *Clostridium sporogenes* has been generally applied to the organism concerned. As with all groups of indicators of pollution, it has its advantages and disadvantages. First of all, however, it is necessary to determine whether the group is always present in contaminated milks and absent in clean milks.

In applying the test to milk quite a number of investigators have been concerned. Savage added one ml., 10 ml., and 20 ml. to tubes of freshly sterilized milk and after heating at 80°C.(176°F.) for 10 minutes to destroy the aerobic vegetative cells, incubated under anaerobic conditions. Finally Savage modified his method by the use of small tubes four inches long and one-fourth inch in diameter. Into 10 of these tubes he placed two ml. of the milk and incubated anaerobically. He then established the following "standards":

0 or 1 tube positive = good milk

2, 3, or 4 tubes positive = unsatisfactory milk

Over 5 tubes positive = bad milk.

Weinzirl's Anaerobic Spore Test as an Indication of Contamination of Milk. Weinzirl²²³ has used the anaerobic spore test for determining the presence of manural matter in milk. He claims that this test is superior to either the counts of the bacteria or the visible dirt tests. The simplicity of the test, along with the apparatus, makes it one that is easily applied. The test is carried out as follows: One-half to one ml. of melted paraffin is placed in a 15 mm. test tube which is plugged with cotton and sterilized either by dry or moist heat. By means of a sterile pipette, five ml. of milk under test are placed in each of five tubes containing paraffin. The tubes containing the milk and paraffin are then placed in the Arnold sterilizer and heated to 80°C.(176°F.) for 10 to 15 minutes. This treatment melts the paraffin which rises to the surface, where it hardens on cooling and forms an anaerobic seal. The heat also expells oxygen absorbed by milk, thus rendering anaerobiosis more complete. All the vegetative bacteria are killed by the heat, only the spore forms remaining. The tubes are then incubated for three days at 37°C.(98.6°F.). If anaerobes are present, gas will be formed which will lift the paraffin plug in the tube. Two positive out of five tubes shows excessive pollution.

Procedures for Determination of Sporeforming Bacteria in Certified Milk.¹⁶¹ The following test is a modification of that described by Weinzirl. Into clean, dry test tubes plugged with cotton, place about 2 ml. of petrolatum and sterilize them in the hot air oven at 160°C. or over for at least one hour, or until the cotton begins to turn brown. Ten ml. of each milk to be tested are pipetted into each of 10 of the above tubes. The tubes of milk are then heated in a water bath at 80°C. for 15 minutes. During this time

222. Hussong and Hammer. 1930. J. Bact. 19, 89-99.

223. Weinzirl. 1915. Amer. J. Pub. Health 5, 862-866; 11 (1921), 149-152.

the petrolatum melts and comes to the surface of the milk. The tubes of milk are then to be cooled and incubated for 72 hours. Gas formed in the milk raises the petrolatum up the side of the tube. Digestion is indicated by clearing of the milk. Certified Milk should rarely show gas formation, coagulation or digestion in any of the tubes. Other grades of milk, whether pasteurized or raw, usually show gas formation, coagulation or digestion in most of the tubes.

Ayers and Clemmer²²⁴ found the Weinzirl test of doubtful value. They found no correlation between the number of positive tubes and the amount of manure. They stated that if the test was carried out with 10 tubes holding 20 ml. each, there was some indication of the methods of production. These conclusions of Ayers and Clemmer were confirmed by Hudson and Tanner,²²⁵ who examined over 100 samples of milk brought to a commercial dairy. They compared the anaerobic spore test proposed by Weinzirl to the amount of dirt in the milk and the number of the bacteria as determined by the Frost plate. Cooledge and Goodwin,²²⁶ however, found the Weinzirl test of value when used along with the pH score. Ritchie,²²⁷ after using the anaerobic spore test for judging the quality of milk, concluded that its value was very slight.

Among anaerobic bacteria *Clostridium welchii* has a significant position. Since it is known to be the cause of severe infections in human beings, its presence in foods has been viewed with suspicion by some bacteriologists. This organism has been discussed in this book in several other places. Generally speaking its presence in foods is considered to be without significance. Whether this is the correct position to assume may not be known at present. North²²⁸ searched for this organism in "certified," Grade A. and "market" grades of milk, using the old "sporogenes" anaerobic test applied directly to the milk but using 10 tubes of about 20 ml. each for each test. Few or no *Clostridium welchii* organisms were found in any of the 10 tubes of certified milk and in only one or two of the tubes of Grade A pasteurized milk. The market milk showed a positive reaction in from five to 10 tubes. These observations were made on a large number of samples from three cities. North believed that *Clostridium welchii* might be an important cause of diarrhea and other intestinal infections in children. On this question, however, no agreement of opinion exists.

• **Fungi in Milk.** As might be expected various fungi have been found in milk supplies. As far as can be determined none of the higher fungi have been proven to come directly from the cow's udder. This would mean then that they have reached the milk from dirty utensils, dust in the atmosphere, and other sources. Among the more common fungi in milk is *Oospora lactis*. Its presence in milk has been reported by many different investigators. Neill²²⁹ reported presence of common molds in dairies. Most of his attention to them was directed at their control and elimination which involved, in general, effective cleaning and washing.

Cummins, Kennelly, and Grimes²³⁰ also reported the presence of numerous fungi in milk. Many of these species had not been reported before although their presence might be expected in view of the possible sources of contamination.

Another class of fungi which has caused considerable trouble in milk are the lactose-fermenting yeasts investigated by Hastings²³¹ and Ram-Ayyar.²³² These organisms attack lactose with abundant gas formation and thus are able to bring about fermentations in milk and dairy products. Nelson²³³ separated the white yeast from dairy products into four groups. He did not consider them to be of any great importance in dairy products. Dombrowski²³⁴ found yeasts to be present in all samples of milk and milk products. The species which he isolated fell into the *Torula* group more than into the *Saccharomyces* or *Mycoderma* group. The strains which he isolated were not limited to alcoholic fermentation but were found to produce colors and flavors undesirable in milk.

Body Cells or Leucocytes in Milk. Various body secretions contain cells discharged from tissue. Milk, therefore, may also contain such cells which originate from tissues with which it comes in contact in the cow's body. On account of similarity in appearance, they have been generally called leucocytes. When such cells were first observed in milk the question immediately arose as to their significance. Some of the earlier investigators believed that they possessed sanitary significance, and thus, a long line of experiments was made necessary to test the validity of this opinion. Stokes and Wegefarth²³⁵ were among the first to look with suspicion on these cells for they called them "pus" cells. Breed²³⁶ could find no evidence that they were harmful or that they indicated undesirable conditions in the udder. Russell and Hoffmann²³⁷ reported a wide range in the cellular content of milks that were apparently normal and safe for use. Pennington and Roberts²³⁸ believed that there was a relation between the number of leucocytes and the condition of the udder. Winkler²³⁹ and Hewlett, Villar, and Revis²⁴⁰ believed that cells found in normal milk were not leucocytes but young epithelial cells, and cells of the germinal layer. Prescott and Breed²⁴¹ and Breed²³⁶ made extensive studies, results of which still confirmed Breed's earlier position that these cells were without sanitary significance. They observed considerable variation in the numbers of leucocytes. Savage²⁴² could not confirm Bergey's²⁴³ opinion

that a relation existed between leucocytes and streptococci. Breed²³⁶ published a bulletin from which the following quotation is taken:

"In other words, the relationships between the number and types of leucocytes in milk and the conditions that give rise to variations in numbers and types of these cells are so complex that they cannot be summarized in any simple way. The only relationship that stands out sufficiently distinct to have been utilized in a practical way in routine microscopic examinations, is that excessive numbers of leucocytes predominantly of polynuclear types, accompanied by long-chain streptococci and particularly when phagocytes containing bacteria are present, indicate streptococcic udder infections with practical certainty. If one or more of the specified conditions are lacking, then the indications become less certain. On the other hand, milk containing small numbers of leucocytes of any kind and no indication of abnormal bacterial infection may certainly be regarded as normal so far as microscopic examination is concerned. When conditions intermediate between these two extremes are found, interpretation of microscopic findings are difficult and uncertain."

Breed²⁴⁴ and Hucker²⁴⁵ again stated that mere presence of epithelial cells in milk was not very significant from the sanitary standpoint. However large numbers (500,000 cells per ml.) from individual quarters indicates an abnormal condition.

Wilson¹⁶ found the leucocyte content of milk of little value in grading. The total number of cells was subject to great variation depending upon a number of factors whose exact importance it was difficult to determine. Prouty²⁴⁶ stated that there was reason to believe that milk secreted from absolutely normal udders contained, as a rule, less than 100,000 cells per ml. In publications of various investigations, the number of cells which might be present in normal milk have been reported to vary from 225,000 to 930,000 per ml. Variations even occur between the different quarters of the same udder. He mentioned the fact that Breed had recorded an instance in which one udder gave milk containing 54 million cells per ml. without showing any evidence of active infection. Wilson believed that a uniform count might be of considerable value in the study of individual cows by veterinarians. *Brucella* infections did not increase the leucocyte content of milk according to Prouty.²⁴⁶

Stoke's²⁴⁷ Method for Leucocytes in Milk. Centrifugal sediments from 10 ml. of milk are stained and examined under the one-twelfth oil immersion objective. The presence of cells in such a field was regarded by Stokes as justification for excluding an animal from a herd.

Reed's²⁴⁸ Method for Leucocytes in Milk. 1. Fill 10 ml. centrifuge tubes with milk and heat for 10 minutes at 70-75°C. (158-167°F.).

1. Centrifuge the tubes at high speed for 10 minutes. Remove the upper layers of cream and milk with a pipette and refill the tubes with distilled water. Centrifuge again for three or four minutes.

3. Draw off all except one-half ml. of liquid in the point of the centrifuge tube. Wipe out the upper part of the tube with a bit of absorbent cotton fastened to the end of a glass rod. Mix thoroughly the remaining liquid and sediment.

4. Transfer a drop of this mixture to a clean Thoma-Zeiss blood-counting cell and place the cover glass over it. Count the cells under a one-sixth objective. If the num-

ber of leucocytes is low, the entire area of the cell should be counted, using a mechanical stage to move the slide. If their number is large, five or six small squares may be counted and averaged. The average number per small square multiplied by 200,000 will give the number of leucocytes per milliliter in the original milk.

Savage's Method for Leucocytes in Milk.²⁴⁹ The ordinary Thoma-Zeiss blood-counting chamber is employed. Direct counting of the cells is impossible, owing to the opacity caused by the large amount of fat. One ml. of the milk is accurately transferred to a centrifuge tube (about 15 ml. capacity) of the usual pattern, and freshly filtered Toisson's solution is poured in to almost fill the tube. The two fluids are well mixed and then centrifugalized for 10 minutes. The cream is well broken up by a clean glass rod, to disentangle leucocytes carried to the surface, and the mixture centrifugalized for an additional five minutes. All the fluid is then removed down to the one ml. mark, great care being taken not to disturb the deposit. This can be conveniently and readily done by means of a fine glass tube connected to an exhaust pump. Theoretically, all the cellular elements present in the original one ml. of milk are now present in the one ml. of fluid. The deposit is thoroughly mixed (with a wire), and distributed through the one ml. A sufficient quantity is placed on the ruled squares of the Thoma-Zeiss apparatus, and the cover glass put on. The number of cells is counted in a number of different fields of vision, moving regularly from one field of vision to another. The diameter of the field of vision is ascertained before counting by drawing out the microscope tube until an exact number of sides of the squares spans a diameter of the field of vision.

The number of cellular elements per cubic millimeter of milk = $\frac{56,000y}{11d^2}$, where y = the average number per field of vision, d = the number of squares which just spans the diameter. d is determined once and for all by marking the microscope draw tube so that only 20 fields have to be counted, and the figures substituted in the formula.

Doane-Buckley²⁵⁰ **Quantitative Method for Estimating Leucocytes in Milk.** With this method 10 cc. of milk are centrifuged for four minutes in graduated sedimentation tubes, at an approximate speed of 2,000 r.p.m. The cream is lifted out with a cotton swab, care being taken to get as much as possible of the fat. It is then centrifuged one minute more and the cream again removed with a cotton swab. Any fat remaining in the milk interferes seriously with the counting, as, if there are more than a few globules they form a layer on the top of the liquid in the counting chamber, and, as the leucocytes settle to the bottom of the chamber, it is difficult to see through the fat. It is only with cows giving milk difficult of separation where this trouble is experienced, and with such animals considerable care is necessary in removing all the cream gathered at the top of the sedimentation tube. The method of removing the fat with cotton is the best one that has occurred to us, and it is the only part of the process that does not operate with entire satisfaction in every instance.

Following the removal of the cream, after the second centrifuging, the bottom of the tube will contain a portion of the sediment which is easily seen. This sediment may, in extreme cases of cows suffering from garget amount to as much as one cc. Ordinarily it will be considerably less than one-half cc. The amount varies considerably with the number of leucocytes, but not absolutely. The milk above this sediment is removed with a small siphon, which can be easily arranged with bent glass tubes drawn to a fine point and supplied with a small rubber end pinch cock. In using the siphon it is better to keep the point near the surface of the milk in the tube in order not to agitate the precipitated leucocytes and draw a number of them off with the milk. The milk in the tube may be siphoned within an eighth of an inch of the sediment in the tube. This will usually be below the one-half-cc. mark. Two drops of saturated alcoholic solution of methylene blue are then added, thoroughly mixed with the sediment by shaking, and then set in boiling water two or three minutes to assist the leucocytes in

249. Savage. 1914. *The Bacteriological Examination of Food and Water*. Cambridge Univ. Press.

taking the color. The contents of the tube can be boiled by holding it directly in the flame, but it has no advantage over the use of the water bath, and it is very likely to break the glass. After heating, some water is added to the tube to render the color less dense. Ordinarily filling the tube to the one cc. mark will be sufficient, and this quantity gives an easy factor for calculating the final results.

In putting this liquid containing the leucocytes into the blood counter considerable care is necessary, owing to the tendency of the leucocytes to sink to the bottom. At this place a capillary tube is used and the cover glass was held in one hand ready to cover the chamber as soon as the drop was transferred to the counting chamber. After placing the glass cover over the chamber, about a minute is allowed the leucocytes to settle to the bottom of the chamber. There are very few foreign bodies likely to be mistaken in counting for leucocytes. Ordinarily the polynuclear leucocytes predominate and the stained nuclei with the unstained surrounding cell show up very distinctly. A few small leucocytes with large nuclei may be found and these may be confounded with yeast cells until the worker becomes familiar with the distinction.

As regards counting we have taken a standard with a cubic centimeter as a basis quantity of milk, though we are, of course, aware that the corpuscles in the blood are enumerated with a cubic millimeter basis. We adopted the centimeter largely for two reasons. In counting bacteria in the milk the cubic centimeter is always the basis employed. Simply because the leucocytes were derived from the blood seemed to be no reason why the same basis for counting should be employed as was used with the blood, while to the ordinary bacteriological worker to whom this work will fall, if ever adopted to any extent, the cubic centimeter standard would be a little more easily comprehended because more frequently used. The blood counter holds $1/10$ c. mm. and $1/10,000$ cc. If 10 cc. of milk are used and the one cc. of fluid is in the tube after siphoning, and the coloring matter and the water used to dilute has been added, then the resulting number of leucocytes in the counting multiplied by 1,000 will be the total number of leucocytes per cubic centimeter in the milk. If a total of 75 leucocytes was counted in the chamber there would be 75,000 leucocytes per cubic centimeter in the milk.

In the actual counting under the microscope a square millimeter of the counting chamber will be found to be ruled off into 400 smaller equal squares. This facilitates an accurate and rapid count. Where the number of leucocytes is not great the entire field can be counted in a short time. Where there is a great number of leucocytes a few squares or sets of squares in different parts of the ruled surface will give approximately the number.

There are occasionally a few variations desirable from these rules, but it may be well to state that the details have been pretty carefully and thoroughly worked over and compared, and it is seldom that short cuts can be made if correct results are desired. The time and speed of centrifuging are placed as low as possible for accurate work. When there is one-half cc. or more of sediment, it is necessary to use more of the methylene blue for staining, as there will be too great a number of leucocytes to make a satisfactory count in the counting chamber, it is better to add water until there are two cc., or sometimes even more in the sedimentation tube.

This method of counting, while long in explaining, is in reality short and simple in application. Moreover, it is based on accurate measurements in every detail, and the results are correspondingly reliable.

The Stewart-Slack ^{251, 252} **Method for Examination of Centrifuged Sediments.** This method is included in the earlier editions of *Standard Methods for the Examination of Dairy Products*. It requires a "Board of Health" centrifuge and tubes. The latter are made from glass tubing one-fourth inch in diameter and are three inches long. The open ends are tightly closed with rubber stoppers. The samples of milk are collected and thoroughly stirred. The stoppered tubes are filled with two milliliters

251. Stewart. 1905. Amer. Med. 9, 486-488.

252. Slack. 1906. J. Infect. Dis. Sup. 2, 214-222.

of such milk and centrifuged. The sediment may be secured as follows: The stopper in the cream end of the tube is first removed. With the cream end down, the cream is removed with a wire and the milk poured out. The other stopper, to which the sediment will adhere, may then be carefully removed and the sediment transferred to a slide.

The sediment is spread in a drop of water over an area of four square centimeters on the glass slide by rubbing the end of the stopper in the drop of water. The film is gently dried, stained with methylene blue, and examined with the 1.9 mm. oil immersion objective.

If the number of bacteria or body cells per ml. of milk is desired, it will be necessary to standardize the field of the microscope in about the same manner as described for the Breed and Frost methods for counting the number of bacteria in milk. If the field has a diameter of .205 mm. it will require 3,000 fields to cover one square centimeter or 12,000 to cover four square centimeters in the entire film. This means that the number of cells seen at one time in one microscope field must be multiplied by 12,000 to secure the number in the entire film. If the diameter of the field happens to be .160 mm. there are then 5,000 fields per square centimeter and 20,000 in the entire film. At least 30 representative fields should be counted.

The interpretation of results is not easy. The character and types of leucocytes may be determined as well as their numbers. If body cells in milk are supposed to indicate bad conditions, they would be expected in much larger numbers during actual infections. To determine the relationship of the presence of streptococci and the number of body cells in freshly drawn milk to pathological conditions Hucker²⁵³ studied a herd of 71 cows for 10 months. No streptococci were found in the milk from any quarter which was free from fibrosis (indurations). Such milk never showed cells in excess of 150,000 per ml., or gave a positive reaction to brom thymol blue. In other words, milk from the truly normal udders did not contain streptococci or an appreciable number of cells. Cells in excess of 150,000 per ml. and streptococci in the milk obtained from these herds indicated that the milk had been secured from udders containing a demonstrable amount of fibrosis. Not all fibrotic udders, on the other hand, showed streptococci or cells in the milk, when studied over a period of months. When more than 500,000 cells per ml. were found in any one quarter, streptococci were at some time noted in the same or some other quarter of the same udder during the lactation period. More than 500,000 cells per ml. in freshly drawn milk signified an infection in the udder.

While body cells may, under some conditions, indicate milk from diseased udders, they have been reported in milk from udders which were normal as far as could be determined. Some of them, of course, may have been abnormal, the condition not being pronounced enough to make itself apparent. Various standards have been proposed, the more recent ones being lower than the older ones. Rosell,²⁵⁴ for instance, believed that a

253. Hucker. 1933. *Amer. J. Pub. Health* 23, 237-245.

254. Rosell. 1934. *Sci. Agr.* 15, 169.

body cell count greater than 250,000 per ml. indicated mastitis. According to Cherrington, Hansen, and Halversen²⁵⁵ normal milk should have fewer than 50,000 cells per ml. while milk from infected udders would usually have more than 100,000. Many factors influence the body cell content of fluid milk. Formulation of any standard would have to consider all of them.

Bacteria which produce defects of appearance and flavor in milk belong to many different genera. Among the more important are fluorescent bacteria. Garrison²⁵⁶ isolated 496 cultures from dairy products which were examined for their effects on various products.

Abnormal Flavors and Appearance in Milk. Like many other foods milk is quite liable to take up odors and flavors from materials with which it comes in contact. Besides these acquired odors are some which may result from bacterial changes in certain milk constituents. These are hard to define, since there may be several definitions for any one abnormality. The following headings include most of the abnormalities of this nature which may occur in milk. Certain individuals in the dairy industry have become quite expert in detecting abnormal odors in dairy products.

Soapy Milk. Fettick²⁵⁷ isolated a bacillus which produced a soapy taste in milk. Finally the trouble was removed by thorough disinfection and cleaning of the utensils. Jaffa described a bacterium from milk under the name of *Bacterium sapolacticum*. It was said to cause a decided soap taste and produced the same flavor when inoculated into sterilized milk.

Moldy Flavor. Fellers²⁵⁸ has reported the *Actinomycetes* as the cause of moldy flavor in milk as well as other foods.

Burnt Flavor. This flavor is often connected with pasteurized milk and has been mentioned as one of the objections to pasteurization. It is an indefinite characteristic. A bacterium was isolated by Sadler²⁵⁹ which was similar to *Bacterium lactici acidi* (Leichmann), to which was attributed the ability to contribute a burnt flavor to milk. It was a facultative anaerobe. Such a flavor in milk would be difficult to define and standardize. It is reasonable that many different aromas and flavors could come under such a description. Hammer and Cordes²⁶⁰ isolated an organism almost identical with *Streptococcus lacticus* which was said to be responsible for burnt taste in dairy products. They proposed the tentative name *Streptococcus lacticus* var. *maltigenes*. Butter and cream with the burnt taste did not reveal this organism on bacteriological analysis. The burnt taste caused by bacteria should probably be distinguished from any alteration in flavor by pasteurization.

Turnip Flavor. This abnormal taste has been attributed to both the presence of turnips in the diet of the cow and to changes brought about by bacteria. The use of sodium nitrate to correct this flavor of milk has been mentioned by Reisz who told of the practice among dairymen of adding 10 grams of this chemical to 100 liters of milk, a practice which should not be allowed. Ritland²⁶¹ published a brief account of a Norwegian experiment. Two cows which were on pasturage were fed turnips out of doors and milked in the stable, and later they were fed hay and turnips in the stable and milked out of doors, the object being to test the absorption of the turnipy odor. No grain was fed at any time. The amount of turnips fed was as high as 2.84 bushels per cow daily. Tests of the milk at different times by a number of persons failed to

reveal any turnipy flavor in the milk. The conclusion was reached that the characteristic taste often observed when turnips are fed is due entirely to the absorption by the milk of the volatile ingredients of the turnips.

Bitter Milk. Practically all dairy products may, at times, be bitter. Different explanations have been advanced. Wolff²⁶² classified the causes of bitter milk as follows:

- (1) Certain foods,
- (2) Physiological process in cows just before and after calving, owing to increase of magnesium sulfate in the milk,
- (3) Action of lactic acid in milk on iron in poorly tinned vessels,
- (4) Activity of bacteria and some of the higher organisms. It is not probable that any particular bitter substance is always present in bitter milk, but that a number of compounds may contribute this flavor to dairy products. He isolated seven different groups of bacteria from grass, clover, etc., which caused bitter tastes in milk.

During the early part of 1901, Harrison²⁶³ investigated the cause of a bitter flavor in milk and cheese, the trouble being encountered in cheese factories in Ontario. A yeast was isolated from samples of bitter curd which was capable of producing a bitter flavor when added to sterile milk. From milk inoculated with this yeast bitter cheese was made in a number of experiments. The yeast, to which the name of *Torula amara* was given, was found in the milk from every farm supplying one of the cheese factories. It was not found in milk drawn into sterile dishes nor in the air of the stables but was found regularly in mixed milk, cheese, whey, and can washings. It was also found on the leaves of certain species of maple. The yeast was not destroyed in cans by washing with water at about 93.5°C. (200°F.), according to the usual farm practice. It grew well in whey in the presence of 1% acid, and acted energetically on lactose. Butter made from cream which had been sterilized or pasteurized and inoculated with the yeast was very inferior in quality, having in the case of pasteurized cans, a pronounced bitter, disagreeable taste.

Lochhead²⁶⁴ isolated two motile rod-shaped bacteria which caused bitter milk. While one produced an evident bitter flavor, it was much more pronounced when the two organisms were grown together.

According to Trillat and Sauton²⁶⁵ aldehyde and ammonia were found in milk having a bitter taste. *Bacillus subtilis* and *Bacillus lactis amari* when grown in milk in pure culture, caused characteristic bitterness and produced aldehyde and ammonia. It was stated that aldehyde came from the lactose. Certain other organisms, when inoculated into the milk, did not cause this flavor. Huyge²⁶⁶ gave the cultural characteristics of a bacillus isolated from bitter milk. The organism was destroyed in whole milk by sterilizing at 105°C. (221°F.) for five minutes and in cream by heating at 90°C. (194°F.) for five minutes on three successive days. The thorough application of this method caused the disappearance of this trouble from the dairy under investigation. The investigations of Palmer²⁶⁷ seemed to indicate that bitter flavor was due to lipase action. This fermentation proceeded rapidly at incubation temperature and was characterized by a liberation of fatty acids, including butyric acid, and an increase in the viscosity. A gelatin liquefying bacterium was responsible for the turnip flavor in a case of bitter milk studied by Orla-Jensen.²⁶⁸ The same organisms caused rancid butter.

Hood and White²⁶⁹ inoculated cultures of an organism quite like *Escherichia coli* into milk and produced bitter milk.

Tallowy Flavor. This is a common fault of fresh milk. Tracy, Ramsey, Ruehe²⁷⁰ found that a relatively high temperature, 68 to 80°F., for the

first part of the storage period and bacterial development seemed to decrease the tendency for the occurrence of the tallowy flavor. Contamination with copper salts such as might result from utensils tended to favor the development of this condition. The score of butter made from cream stored for five days under different conditions before churning was higher when made from cream stored for one or two days at 20°C.(68°F.) and for three or four days at 4.4°(40°F.) than when stored for five days at 40°F., and the latter butter showed a very tallowy flavor. Living yeast cells retarded the development of tallowiness in milk, but dead yeast cells and the filtrate from suspensions of yeast had no effect on the development of tallowiness during a storage period at 40°F. Determinations of the oxidation-reduction potential of milk and cream indicated that the activity of bacteria and yeast tended to remove oxygen in their metabolic processes, and tallowiness resulted from the degradation of the fats. A shorter incubation period of 68°F. at the beginning of the storage period, although increasing the bacterial count, had a favorable effect in tending to prevent the tallowy flavor. Winter milk is consequently more liable to have a tallowy flavor than summer milk. Homogenization retarded the development of the tallowy flavor of milk due, it is suggested, to certain physical changes which make the detection of flavor more difficult.

In a study at the Pennsylvania Experiment Station,²⁷¹ it was shown that exposure of certain milk and milk products to sunlight ordinarily resulted in the development of off-flavors designated either as burnt or tallowy. These two appear to be distinct flavor changes, the former predominating in low fat products, the latter in high fat products. Paraffined paper milk bottles used in this study offered considerably more protection to skim milk, whole milk, and buttermilk against the development of burnt flavor than was afforded by clear glass bottles. However, paper bottles were no protection to whole milk or cream against tallowy flavors caused by sunlight. Blue and green colored paper bottles or blue and green cellophane wrappers on paper bottles retarded the development of both burnt and tallowy flavors. Off-flavors were detected first in the milk in glass containers, but the intensity of tallowy flavor in milk and cream was greater in the paper bottle.

Fishy Flavor in Milk. *Bacterium ichthyosmius*, according to Cusick,²⁷² will produce this offensive flavor. Samples of butter inoculated with this organism developed the flavor. It was stated that the organism formed trimethylamine which was responsible for the flavor. That bacteria may not be the sole cause of the fishy flavor in milk is emphasized by Johnstone.²⁷³ Lecithin is said to be present in the milk of cows just freshened; under favorable conditions this lecithin combines with air to form choline; this choline then breaks down to trimethylamine. To prevent this form of fishiness in butter, the lecithin must be oxidized in the cream before the butter is made, or oxidation prevented after the butter has been made. Ruehle²⁷⁴ reported the formation of a disagreeable sickish taste in milk; this was found to be due to a very short rod with which the abnormal condition could be reproduced upon inoculation into sterile milk.

275. Fettick. 1911. Ztschr. Fleisch. u. Milchhyg. 21, 280-283.

Fettick²⁷⁵ studied a species of bacterium, thought to be the cause of a strawberry-like odor in milk. It was isolated from a sample of milk and appeared to have the properties of *Pseudomonas fragaroides*.

Aromatic Odor. An amyl alcohol aroma of milk was found by Cunningham²⁷⁶ to be caused by *Micrococcus caseolyticus*. The odor was especially noticeable when the cows were stabled but soon disappeared when they were pastured. The organism was said to originate from the floor of the stable. Washing and disinfecting the floor stopped the difficulty.

Malt Flavor. A micrococcus of the aureus type may cause an objectionable malt flavor in milk, according to Tracy and Ramsey.²⁷⁷ When an organism of the *Bacillus subtilis* group was also present, a much more pronounced malt flavor resulted. Acid-forming bacteria retarded development of this flavor. The defect was found to be common in raw milk plants during summer. Utensils were a direct source of the large rods; the coccus forms were found in the udders of cows in suspected herds. Neither cocci nor the rods produced gas; they were proteolytic in action. Pasteurization of pure cultures of the cocci at 61.2°C.(142°F.) resulted in their death after 20 minutes, the rods surviving even higher temperatures. The malt flavor developed most rapidly in milk held at 29.4 and 37.8°C.(85 and 100°F.), although a more characteristic flavor was noted in milk held at 20°C.(68°F.). The defect failed to develop in milk held at 15.6°C.(60°F.) for three days.

Oxidized Flavor. This has become a common flavor defect of milk. Its cause is not bacterial so far as is known so it will not be discussed at length in this book. Barkworth²⁷⁸ found that it could be induced by copper contamination, as did Webb and Hileman.²⁷⁹

Oiliness or Rancidity of Milk. This is largely of chemical origin. According to Mattick²⁸⁰ oiliness in milk occurs during late autumn, winter, and early spring and is widespread. Search for a bacterial cause was not successful. At one farm replacement of an old cooler by a new one resulted in the disappearance of the taint. Bacteriological examination of the cooler gave no result, but it was noted that in the old cooler the tin plating had in part worn away and exposed the copper beneath. Laboratory experiments were made with fresh milk and a similar cooler. Milk passed over the cooler developed oiliness; at summer temperatures no oiliness was found. Oiliness is due to a reaction catalyzed by the copper; oxygen must be present.

During recent years, much has been done on bacterial decomposition of fats to fatty acids and glycerol. The former may have pronounced odors which would be most objectionable in milk. They would probably cause the condition known as rancidity. Bacteria which decompose fats are widespread and could be expected in dairy products. Methods for detecting them are given in Chapter 2, with a discussion of microorganisms involved. Hammer and his students at Iowa State College have

studied these organisms in milk and dairy products. Collins and Hammer²⁸¹ found several lipolytic bacteria in various materials, such as water, dairy products, and plant equipment. *Pseudomonas fluorescens* and *Pseudomonas fragi* were identified.

Further investigations on the distribution of *Pseudomonas fragi* by Morrison and Hammer²⁸² revealed its presence in 29 of 176 samples of milk delivered during the cool seasons to an Iowa plant; the organism was also found in many samples of soil, water, feed, and bedding and in swab cultures from different utensils. Presence of *Pseudomonas fragi* in such materials makes it easy to explain its origin in milk.

Blue Milk. This term indicates in a good way the change concerned. At one time it was one of the commonest color changes brought about by bacteria in milk and consequently received much study. Schultze²⁸³ cited cases from which *Bacillus syncyanum* could be isolated from milk which was taken under sterile conditions from the udders of eight cows. The infection was usually present in all of the quarters of the gland. Wolff²⁸⁴ believed that the occurrence of blue milk should be ascribed to *Bacillus syncyanum* and *Pseudomonas cyaneofluorescens*. The former bacterium formed small blue spots on the surface of milk which rapidly increased in size and extended downward. It was dependent upon the presence of lactic acid bacterium, without which the formation of pigment could not continue in strongly acid milk. There were other organisms capable of coloring milk blue. It was thought that though these microorganisms of blue milk are easily killed by pasteurization, the ordinary temperature of from 68 to 70°C. was low unless kept up for 30 minutes. Flies and water are common carriers of these organisms and are the sources of infection of milk. A more complete investigation was reported by Hammer.²⁸⁵ Careful study of the organisms involved proved it to be *Bacillus cyanogenes*. The organism isolated was examined morphologically, culturally, and biochemically. In its action in milk the organism was found to produce a color in raw milk, in pasteurized milk, although the color produced was markedly influenced by the previous treatment of the milk.

Raw milk invariably developed a color sooner than pasteurized or sterilized milk and the color was also a brighter blue as a rule, being in some cases a sky blue. Pasteurized milk inoculated with the organism developed a more intense color than the sterilized milk, and in some cases (apparently influenced largely by the organisms surviving pasteurization) the color developed approximated that developed in raw milk.

Yellow Milk. This color change is less common than blue milk. One case was studied by Hammer²⁸⁶ who reported morphological, cultural, and biochemical characteristics of two organisms, isolated in the dairy bacteriological laboratory and peculiar in their action on the cream layer of milk in producing a decidedly yellow color in it without breaking down the fat. One organism was named *Bacillus synxanthus*.

Red Milk. This also is a less common color change in milk. Some of the earliest observed cases of red milk were due to *Serratia marcescens* (*Bacillus prodigiosus*). This organism is widely disseminated in nature and therefore is one of the commonest causes of this color change. A close relative of this organism *Serratia rubefaciens* (*Bacillus rubefaciens*) has also been found. There is no evidence that red milk is harmful.

Germicidal Action of Milk. The number of bacteria gaining entrance to milk is determined by conditions under which it is produced. After the bacteria are in the milk, their development is influenced by several factors. A number of investigators who made counts on fresh milk at

frequent intervals reported a decrease in the number of bacteria which could grow on agar plates during the first few hours. In general, the lower the temperature at which the milk was held, the longer this period was. Investigations were then instituted to determine the reasons for the phenomenon. The earlier literature of the subject was reviewed by Rosenau.²⁸⁷ Different explanations are possible. Some will be tabulated below with the names of the investigators whose work supports them.

1. Decrease in bacterial numbers is due to presence of specific antibodies.

This explanation was suggested by the fact that the blood, as well as other body fluids, contains bactericidal substances capable of destroying bacteria. Fokker,²⁸⁸ who observed the phenomenon, leaned to this explanation. Woodhead and Mitchell²⁸⁹ believed that milk contained opsonins which were detrimental to bacteria. The high opsonic index observed for milk was suggested to play a role in the protection of children from tuberculosis. König²⁹⁰ believed that fresh milk contained substances of hemogenous origin which gave it germicidal properties. Hesse²⁹¹ explained the reduction in numbers of bacteria on the basis of the presence of vital principles. Basenau²⁹² disagreed. Schenk²⁹³ found a bactericidal substance in milk. Behring²⁹⁴ thought that milk had bactericidal property similar to that possessed by blood. Meinicke²⁹⁵ agreed for cholera organisms, but not for the members of the typhoid group. Moro²⁹⁶ believed that a true bacteriolytic alexin was present in milk. Heinemann and Glenn²⁹⁷ believed that their results supported the existence of agglutinins, which clumped the bacteria and caused a decrease in numbers. This view was also held by Rosenau.²⁸⁷ The work of Chambers,²⁹⁸ Meier,²⁹⁹ Curran,³⁰⁰ and Stek³⁰¹ probably supports this explanation also. Mazé³⁰² believed that alexins were present. The presence of antibodies is also supported by recent work by Henninger³⁰³ and Jones and Little.³⁰⁴ Jones and Simms³⁰⁵ attributed germicidal action to the presence of a substance called "lactenin." Little³⁰⁶ also believed in a specific substance in the milk of all cows which inhibited mastitis streptococci for a definite period. He believed it was an inherent factor because milk of young cows contained about as much of this substance as the milk of older cows, although

its concentration varied among different cows and even in the different quarters of the same cow. Support for the presence of definitely antibacterial agents in milk also was indicated by results of investigations by Dold, Wizemann, and Kleinen.³⁰⁷ They observed an inhibitory effect of milk on bacteria which was attributed to the presence of "mutines" and "inhibines." With few exceptions growth of all of the bacteria tested was less on the raw than on the heated milk-agar plates. Whether these differences were of sufficient magnitude to justify the extensive conclusions reached by these authors is doubtful. Certainly there was little need for another set of names for agents which have been found in milk by many others before.

2. Presence of acid destroys the bacteria. This view was held by Weigmann and Zirn,³⁰⁸ who studied the behavior of *Vibrio cholerae* in raw milk. Bardelli³⁰⁹ believed that increased acidity explained the lack of growth. It is difficult to understand how this would function in the early history of milk after it has left the udder.

3. Decrease in bacterial numbers owing to death of bacteria which find milk unsuitable for development. This reasonable explanation was offered by Stocking.³¹⁰ It does not necessitate existence of specific bactericidal substances. Antagonisms between microorganisms would function here.

4. A phenomenon connected with transfer of organisms to a new medium. This places the explanation of the phenomenon on the same basis as the "lag phase." Coplans³¹¹ pointed out that there is a period of latency when bacteria are transferred to new media. During this period, there is usually no increase in numbers. Sherman and Curran³¹² believed that the explanation was in a better knowledge of bacterial growth curves.

These explanations are probably not the only ones which could be offered. They probably are the more important ones. The preponderance of evidence favors the existence of specific antibodies in the milk. The data, however, to support this view rest almost entirely on the fact that bacteria grow better in heated milk than in raw milk, which would seem to indicate that some thermolabile substance is destroyed.

Several different investigators believe that no germicidal action exists. Schottelius,³¹³ Kitasato³¹⁴ and Friedrich³¹⁵ agreed with Basenau²⁹² that milk was not germicidal for *Vibrio cholerae*. Moro denied the germicidal action of milk on *Eberthella typhosa*, *Escherichia coli*, and dysentery bacilli. Knox and Schorer³¹⁶ believed that the germicidal properties of milk had been greatly overemphasized. Confusion of the subject is partly due, according to Evans and Cope,³¹⁷ to different methods of working.

Many of those who have studied the question have observed a specificity of the milk of certain cows for certain bacteria. Milk of various species also differs. Cozzolino³¹⁸ experimented with milk of asses, cows, goats, and human beings, finding the milk of the ass strongest and that of the goat weakest. Human milk was found to be especially active toward *Escherichia coli*. Klimmer's³¹⁹ work partially confirmed this. Heinemann reported that same bacteria were killed, while others were not, as did Evans and Cope, Chambers,²⁹⁸ Meier,²⁹⁹ Hanssen,³²⁰ and others. Meier and Chambers found that the milk of various animals differed in intensity of germicidal property. Mazé related this to the time of year and "regimen" of the cow. Hanssen held the same opinion.

Slimy or Ropy Milk. This is an abnormal fermentation of milk caused by the growth of certain bacteria which form capsules. It should be sharply distinguished from stringy milk, which results from inflammatory infections of the udder. Much work has been done on ropy milk and, fortunately, most of the published work is in agreement. A fine historical survey was published in 1916 by Buchanan and Hammer.³²¹ Harding and Prucha³²² have characterized the trouble as follows:

The term ropy or slimy is applied to milk which has become noticeably more viscous than ordinary milk. When this ropiness is only slightly developed, it is ordinarily overlooked. It is sometimes noticed from the fact that the milk pours more slowly, or because the last portion drips from the container with the formation of an evident thread of milk.

Where the viscosity is more pronounced, the milk may be drawn out by means of a fork or similar object into threads. In extreme cases these threads may be fine and silky, and more than a foot long, though more frequently they break when only an inch or less in length.

In extreme cases, the milk takes on almost the consistency of a sticky, stiff dough, and a cup of it may be inverted without the milk being spilled.

Ropy milk should not be confused with the results of garget. Garget is an inflamed condition of the udder of the cow, and milk as it comes from such inflamed udders frequently contains white masses or strings of coagulated material. Milk which becomes ropy, on the other hand, comes from healthy udders and is normal when drawn, but the ropiness may appear at anytime after twelve hours.

There are at least three common and distinct types of ropy milk: (1) the ropiness produced in milk drinks by the Bulgarian bacillus, (2) the ropiness in starter for butter-making, resulting from the degeneration of the starter culture, and (3) the ropiness which appears in sweet milk.

Ropiness was one of the first abnormal fermentations observed in milk. Some people have become so accustomed to ropy milk that they prefer it to ordinary milk. Schmidt³²³ showed that the fermentation could be brought about in sweet milk by adding a few drops of ropy milk. Adametz³²⁴ isolated an organism, *Achromobacter metalcaligenes*, as the cause. Since that time Buchanan and Hammer,³²¹ Harding and Prucha,³²²

Cole and Hadley,³²⁵ Marshall,³²⁶ Conn,³²⁷ Hopp,³²⁸ Sachmann,³²⁹ Ward,³³⁰ Gruber,³³¹ Burri,³³² Sato,³³³ Dornic and Daire,³³⁴ and many others have reported substantiating evidence.

Ward³³⁵ isolated Adametz's organism in an outbreak of ropy milk, but had difficulty in locating the source of the organisms. No complaint followed the use of milk within a few hours. When it was allowed to stand, however, ropiness developed. Ward³³⁰ believed that the bacteria got into the milk from water. He reported that the trouble could be stopped by adding one part of potassium bichromate to water. Tilmans, Konig, and Spiekermann³³⁶ made ropy milk artificially with several bacteria and observed a marked difference in the type of rope. Hohl³³⁷ isolated *Micrococcus pituitoparus* from straw. It caused ropiness in both raw and sterilized milk. An organism similar to *Bacterium g ntheri* which produced ropiness in milk at 37°C.(98.6°F.) to 40°C.(104°F.), was isolated by Burri. Dornic and Daire isolated an organism forming rope from serum obtained in the manufacture of casein. The viscid substance formed was apparently a carbohydrate.

Harding and Prucha and Ward believed that rope-forming organisms were commonly present in milk. The former investigators stated that much ropy milk was overlooked because the consumer was not acquainted with it. Ward stated that the occurrence of ropy milk depended upon the following factors: (1) the necessary organism; (2) suitable temperature for multiplication; and (3) sufficient time for growth to a recognizable degree at the temperature to which the milk is subjected. Ward believed that ropiness was a constant possibility in milk, but that it is repressed by the conditions under which milk is usually handled. This means that the organisms are normal ones in milk, and when an outbreak of ropiness occurs the milk has been handled under conditions favorable for development of the capsulated organisms.

Many different species of bacteria may cause milk to become ropy. A comprehensive key of these bacteria was published by Buchanan and Hammer.³²¹ Typical organisms were described by Laxa³³⁸ and Long and Hammer.³³⁹ Laxa named his organism *Viscobacterium lactis faetidum*, while Long and Hammer used the name *Alcaligenes viscosus*. Even *Escherichia coli*-like bacteria have been isolated from ropy milk. Sadler and Middlemass³⁴⁰ isolated *Escherichia neapolitana*. It was killed by heating

to 63°C. (145.4°F.) for 10 minutes. *Escherichia-Aerobacter* organisms were found by Sarles and Hammer³⁴¹ to produce various defects in dairy products. Among them was ropy milk caused by *Escherichia neapolitans*, *Aerobacter aerogenes*, and *Aerobacter cloacae*. Ropiness in pasteurized milk was due to contamination after pasteurization.

Microorganisms producing ropy milk probably originate in the various objects with which milk comes in contact. They reach milk from air and dust. Feeds were found to contribute them by Stark.³⁴² Thousands of ropy milk-producing bacteria were observed in alfalfa hay, clover hay, chaff, soybean meal, and cottonseed meal. Other feeds contained smaller numbers. In one outbreak studied by Kelly³⁴³ the rope-producing bacteria were found to be contaminating pasteurized milk from pipes through which raw milk had passed. The trouble was aggravated by milk returned from wagons and stores. One lot contained 32,000 ropy-milk bacteria per ml.

Prevention of ropy milk is accomplished by constant attention to bacterial quality of raw milk, efficient pasteurization, sterilized utensils, and constant refrigeration. Milk may contain these bacteria without becoming ropy if it is kept cold. Once a dairy or milk-processing plant becomes infected by rope-producing bacteria they are eliminated by thorough cleaning of the plant in the bacteriological sense. This involves generous use of hot water and steam and even use of chlorine compounds as disinfectants. Perkins³⁴⁴ and Harding and Prucha³²² advised use of calcium hypochlorite in a concentration of 12 ounces per 100 gallons of water. Apparently the efficiency of chlorine compounds varies. Johns³⁴⁵ found the less alkaline hypochlorites to be very effective against five ropy milk and two bitter milk bacteria. Some Gram-positive bacteria were more or less resistant to such solutions.

Stark's³⁴² Method for Determining Presence of Ropy-Milk Organisms in Milk. Collect samples of incoming milk in sterile containers and incubate at 15.6°C. (60°F.) for 48 hours. After 24 hours test the samples by touching the top layer of milk, especially around the edge of the container, with a sterile toothpick. Those samples which show no evidence of ropiness at this time may be retested after 48 hours' incubation. The influence of various steps in processing of the milk may also be determined in the same manner.

Believing that *Escherichia-Aerobacter* bacteria cause more outbreaks of ropy milk than do other bacteria, Curtis³⁴⁶ recommended formate ricinoleate broth for detecting these organisms in milk. Samples collected at various stages of plant processing and showing gas formation may or may not become ropy but samples showing no gas will rarely develop ropiness when placed at 15°C. (60°F.) to 18.3°C. (65°F.).

Medical Milk Commissions and Certified Milk. Medical Milk Commissions originated in 1890 when the Medical Society of New Jersey attempted to improve the quality of milk. A committee of this society studied the situation and later tried to induce the state to take over the work. This attempt failed because of lack of funds. Finally, plans were made by

physicians themselves to supervise milk production. A dairyman who already had high standards was interested and willing to cooperate. In this way the first Medical Milk Commission was formed, and the production of what is known as "certified milk" was begun. The first commission was known as "The Medical Milk Commission of Essex County, New Jersey." In order to protect the term "certified milk" from being degraded by dairymen not under contract with a Medical Milk Commission, it was registered in the U. S. Patent Office in 1904 (Lane³⁴⁷). It was not intended that the term was to be restricted to this one Medical Milk Commission, but that any Medical Milk Commission could use it. Certified milk, then, is milk produced under a legal contract between a Medical Milk Commission and a dairyman and conforms to certain requirements. Certified milk is well described in the following quotation which is taken from Lane's discussion.

The objects of this commission are to establish correct clinical standards of purity for cow's milk; to become responsible for a periodical inspection of the dairies under its patronage; provide for chemical and bacteriological examinations of the product, and the frequent scrutiny of the stock by competent veterinarians; to promote only professional and public interests.

The following are three general requirements or standards for the milk: (1) An absence of large numbers of microorganisms, and the entire freedom of the milk from pathogenic varieties; (2) Unvarying resistance to early fermentative changes in the milk, so that it may be kept under ordinary conditions without extraordinary care; (3) A constant nutritive value of known chemical composition, and a uniform relation between the percentage of fats, proteins, and carbohydrates.

Certified milk has been called the honor product of the industry and has been produced under exacting conditions which have been faithfully carried out. It is the only milk produced today under uniform national standards.¹⁸¹

Bacteriological Standards for Certified Milk. These have been critically reviewed by Brown.³⁴⁸ The bacteriological standards require that it shall not contain more than 10,000 bacteria per ml. and that pasteurized, certified milk shall not contain more than 500 bacteria per ml. These counts are to be determined in a special agar, the formula for which is given in the chapter on "Media." Logarithmic and arithmetical averages were discussed by Brown who stated that the former minimized too effectively individual faults on particular occasions. The American Association of Medical Milk Commissions does not recognize judgment of certified milk by averages because it requires that certified milk have a uniformly low count rather than an average low count. Fewer than 10 coliform bacteria per ml. are permitted in raw certified milk; in pasteurized certified milk there shall be no such organisms. Provision is also made for examination of the milk for hemolytic streptococci and sporeforming bacteria. The former bacteria would give some information about the condition of the udder, for control of mastitis is essential in certified milk control. The spore test is of value in maintaining a clean milk. The methods of analysis adopted by the American Association of Medical Milk Commissions for

examination of certified milk are given in other places in this book. The American Association of Medical Milk Commissions publishes them in a small pamphlet.¹⁸¹

Pasteurization of Certified Milk. Previous to 1935 certified milk was mainly raw milk. Pasteurization is required to make milk safe. Certified milk was probably clean but it was not necessarily safe milk. The American Association of Medical Milk Commissions,³⁴⁹ at their annual meeting at Atlantic City, June, 1935, voted unanimously for permissive pasteurization of certified milk. Although certified milk has long been recognized as a superior product and has always been produced in accordance with uniform national standards, there has been opposition to its pasteurization. Investigations have shown that pasteurization does not impair the nutritional value of the milk.

Previous to 1935 pasteurized, certified milk had been recognized in Boston in 1928. According to Eustis³⁵⁰ this has lowered the counts to 100 or under.

In Boston pasteurization of certified milk increased its sale and the demand for pasteurized, certified milk now exceeds that for unpasteurized, certified milk. This experience has been duplicated in other communities and it is to be expected that the more extensive adoption of the process will result in greater public appreciation of an already superior product.

Dirt or Sediment in Milk. Dirt is objectionable in any food. Estimation of the amount of dirt in milk has been suggested as a means for learning the conditions attending its production. The sediment test has evident limitations for the producer may strain his milk and remove most visible dirt. Wilson¹⁶ did not consider the test to be of great practical value. In his comprehensive study of procedures for examination of milk, he made no observations on this test. *Standard Methods for the Examination of Dairy Products* of the American Public Health Association give suggested procedures for the test. The general procedure is to pass a pint of milk through a disc and to compare this disc with standard discs.

While cleanliness is to be desired in milk, the chief medical officer of the Ministry of Health of Great Britain³⁵¹ has pointed out the important distinction which should be made between "clean milk" and "safe milk." In spite of the obvious and important distinction between "clean milk" and "safe milk," confusion often exists in the minds of some who are discussing quality of milk. This authority stated that "clean milk" is milk which has been produced and distributed with the minimum amount of extraneous contamination, such as manure from the cow's udder and flanks, dust from the cowshed and dairy, and dirt from the milker's hands, utensils, and milk containers. "Safe milk" is milk which contains no pathogenic organisms. The following paragraph summarizes this argument:

"It is clear therefore that cleanliness by no means connotes safety. It is true that when milk is handled carelessly the conditions which lead to dirty milk also favor con-

tamination with any pathogenic organisms which may be in a position to gain access to the milk, such as streptococci from a milker with sore throat or organisms of the typhoid group which may have gained access to milk or milk vessels from persons infected with such organisms. It should, however, be noted that even a clean milk may be infected in this way, so that cleanliness is no guarantee of safety from adventitious human infection though in general it may be expected somewhat to reduce the possibility. Cleanliness is, of course, no safeguard whatever against infection conveyed to the milk from a diseased cow. Milk obtained from a herd infected with tuberculosis or contagious abortion is never safe no matter how cleanly it may be produced. Cleanliness, however, is important from an esthetic and commercial standpoint. Dirty milk is not only esthetically objectionable but it has also poor keeping qualities and for this reason alone reputable firms are anxious to obtain their supplies as clean as possible. While therefore cleanliness is desirable cleanliness is not enough. Safety is the really important consideration and in present circumstances the ordinary raw milk supply can never be regarded as safe. To ensure its safety, that is to say, its freedom from pathogenic organisms, suitable heat treatment such as that afforded by efficient pasteurization is essential."

Some early investigations were carried out to determine whether the results of a sediment or dirt test applied to milk could be used to determine the condition under which the milk was produced or handled. These results were also compared with the results of the plate count, for this was then the main method for examining milk. As might be expected the correlation was not always close, for various factors influenced the results of each test. The kind of dirt influenced the results secured with the sediment test and the types of bacteria, the results of the standard agar plate. Schroeder³⁵² found that the amount of dirt in fresh milk correlated well with the bacterial count. This was also borne out by the work of Reed and Reynolds.³⁵³ On the other hand, Campbell³⁵⁴ reported that the amount of dirt which appeared on the discs of the sediment tester was no criterion of the number or kind of bacteria in the milk. Ayers, Cook, and Clemmer,⁷⁰ when using fresh milk, found a relation between the amount of dirt and the bacterial count, as did Backhaus.³⁵⁵ He stated that about 50 per cent of fresh cow dung, dissolved in the milk, could not be estimated by the sediment test. The bacterial count would probably be affected by this amount of foreign matter. Ayers, Cook, and Clemmer found that relatively large amounts of cow manure had to be picked up by milk to cause significant increases in the bacterial count. They found an average number of 50,000,000 bacteria per gram in fresh manure. On this basis, addition of .5 gram of wet manure to a pint of milk would increase the bacterial count 52,854 per ml.; other data were given for lesser amounts.

A number of sediment discs made from milk with known amounts of dirt were shown. It was brought out that .5 gram of wet manure represents a quantity far in excess of that found in the milk produced on an average farm; it was therefore believed to be evident that this excessive quantity of manure would only add 52,854 bacteria per ml. If .1 gram of manure were added to a pint of milk, that quantity would add only

10,571 bacteria to each ml. It is evident then, that the bacterial count is not a means of measuring manurial pollution which would ordinarily occur. The same conclusions were reached by Harding, Prucha, Kohman, Weeter, and Chambers,³⁵⁶ who compared dirt contents with bacterial counts.

The use of a small-top pail materially reduced the amount of dirt entering the milk, since practically all entered at the farm during the act of milking. The weight of such dirt was very small. Even when the cows were extremely dirty and were milked into an open-top pail, the dirt in the unstrained milk amounted to only about 10 mg. per quart. Under conditions comparable to those of the ordinary dairy, and when the small-top pail was used, the dirt in the milk was less than five mg. per quart. Under conditions similar to those which obtain in the better class dairies, the amount of dirt was not over 2.5 mg. per quart. The kind of dirt varies with the conditions of the animal. Hair and other material from the coat of the animal will fall into the milk unless the animal is kept clean. Thorough straining, however, removes such dirt to the extent of from 75 to 90 per cent. One must always admit the possibility of soluble dirt entering the milk; such dirt would not, of course, be removed by straining. Harding and his colleagues found a wide variation between the amount of dirt and the bacterial count. In dirt from extremely dirty cows, 1.55 billion bacteria per gram were found. Under the worst conditions, when the dirt in the milk amounted to 10.8 mg. per quart, the increase in the bacterial count of the milk was 17,000 per ml. Under the same conditions, except that the small-top pail was used, the increase in bacterial content owing to dirt was 13,000 per ml. Harding stated that the increase in content of bacteria owing to dirt would be overshadowed by other factors. He further stated that when the bacterial count is used to protect the consumer against undesirable milk, he will not be protected. It was stated that it was entirely possible for the dirtiest milk to pass the most stringent standards, based on bacterial counts, which have been established in connection with the supervision of municipal milk supplies. These investigators failed to take into account that bacteria multiply rapidly in milk. A count of 17,000 caused by dirt might soon cause so many bacteria to be present that the milk would not pass standards. Results of bacteriological examination of fresh cow manure have a bearing on such arguments. Prucha, Weeter, and Chambers³⁵⁷ examined 27 samples of fresh cow manure, finding a variation of 434,000 to 73,200,000 per gram of dry matter. Allen,³⁵⁸ in examination of 50 specimens found between 160,000 and 634,000,000 bacteria per gram in fresh moist feces and in dried specimens between 500,000,000 and 16,800,000,000. Such data would seem to indicate that the bacterial count might be significantly influenced by the addition of a little cow dung to milk.

358. Allen. 1923. *J. Dairy Sci.* 6, 479-482.

In another publication, Harding and Prucha³⁵⁹ continued the discussion just reported. According to these investigators, the plate counts of dirt which may enter the milk may vary from 1,000,000 to 2,000,000,000 bacteria per gram (aerobic count). They classified the sources of dirt in milk as dust, feed, milk remnants, hair, dandruff, soil, and manure, most objectionable of which is manure. These investigators worked under average dairy conditions and also under filthy conditions in order to completely cover the subject. Small amounts of dirt were recovered from the milk and it seemed to have little influence in raising the bacterial count, as determined by the standard agar plate. Dirt from cows possesses an abundant bacterial flora, approximately one and one-half billion per gram. The data secured indicate that the enumeration of bacteria might not give information with regard to the dirt content of milk. However, in an added paragraph, the authors state that the count is, if properly determined, a satisfactory indication of keeping quality.

Ward³⁶⁰ observed a close relation between the color of the cotton discs used in sediment tests and the conditions under which the milk was produced. He believed that sediment tests and temperature determinations of milk at delivery points would indicate those farms which needed attention. He also stated that examination of the dirt on the disc with a lens would indicate quite accurately what faulty conditions existed on the farm furnishing the milk.

Breed,³⁶¹ for the control of the milk supply of Geneva, N. Y. (15,000 population), urged the sediment test in preference to the bacteriological examination. He stated that high counts were due to (1) udders infected with streptococci; (2) poorly washed milk cans; (3) poorly sterilized milking machines; (4) improper cooling. One might consider that these very reasons indicate that the count is valuable for a good milk would not be produced under conditions such as these.

Methods for Estimating the Amount of Dirt in Milk.—Even relatively small amounts of dirt may be observed by examination of the bottom of bottles which have been allowed to stand. Such a method does not have the precision desired in routine control methods. Various methods have been proposed. They were discussed by Schroeder³⁵² and grouped.

American Public Health Association Procedures for the Sediment Test on Milk. These are given in *Standard Methods for the Examination of Dairy Products*, seventh edition, 1939. Pint samples are considered as standard and are to be collected from well-shaken containers. The sample is passed through a cotton disc placed over an opening one inch in diameter. Sediment testers are available which will force the milk through the disc under air pressure. The disc secured on the sample is then compared with standard discs, directions for preparation of which are given. These may be secured in the book referred to above. The fifth edition of *Standard Methods of Milk Analysis* contained photographs of standard discs which had been made by filtering pint portions from two-quart amounts of milk to which 0, 5, 10, 15, and 20 milligrams of dry stable dirt had been added.

Mickle³⁶² criticized the directions given in earlier editions. He found

359. Harding and Prucha. 1921. Ill. Agr. Expt. Sta. Bull. 236.

360. Ward. 1918. Ann. Rept., Internatl. Assoc. Dairy and Milk Insp. 7, 54-60.

361. Breed. 1919. Rev. in Amer. J. Pub. Health 9, 627.

362. Mickle. 1928. Amer. J. Pub. Health 19, 172-178.

it impossible to use the standard discs as guides in Connecticut. He also believed that *Standard Methods* should specify some particular apparatus for making the test. He stated that the sizes of particles on the different standards varied greatly, and that the kind of dirt used in different laboratories varied in color to a greater extent than had previously been thought possible. Mickle suggested these changes in technic for determining dirt in milk:

- 1. The use of pint samples. Where absolutely necessary to use less, the size of sample to be stated plainly on the report.
- 2. The desirability of adopting one type of tester and, particularly, one grade of cotton disc. (Later on Mickle reached the conclusion that it was not always essential that the testers in use be uniform, providing a standard cotton disc is adopted. There are many valid objections against the use of one type of tester under the various conditions that obtain in the control laboratory, the milk-plant laboratory and the field test.)
- 3. All grading to be done against a photograph of standard discs prepared by a central agency and not against standards made by filtering milk to which different amounts of dirt have been added.

TABLE 3
*Chart for Grading Visible Sediment in Milk According to Procedure
Suggested by Mickle*

Terms not to be reported	Terms to be reported	
Milligrams per unit	Sediment score	Cleanliness ratings
.00- .12	0	Clean
.13- .37	25	Fairly clean
.38- .62	50	Acceptable
.63- .87	75	Slightly dirty
.88-1.12	100	Dirty
1.13-1.77	125	Very dirty
1.78-3.75	250	Very dirty
3.76-5.00	500	Very dirty

- 4. The entire disc to be returned to the dairyman because of the difficulty of cutting many discs into two portions showing equal amounts of dirt.
- 5. No attempt should be made to grade as sediment any hair, piece of hay or straw, or large particle of dirt. Those should be reported separately.
- 6. Additional standards are recommended representing, respectively, .25, .50, .75, and 1.00 milligram of dirt per pint, as, otherwise, nearly all milk as sold to the consumer will be classed as "clean."
- 7. The descriptive terms in *Standard Methods* are not apt for use on bottled milk and should be changed. It is hopelessly confusing to have one standard for milk as sold to the consumer and another for milk as received at the milk plant.
- 8. Since the term "milligrams per pint" is not strictly accurate, is cumbersome, and is often misunderstood, it is suggested it be abandoned in place of the term "sediment score" (Table 3). No "sediment score" should be reported within closer limits than the eight figures given in the score. Samples should always be reported both in terms of the "sediment score" and by one of the descriptive terms for "cleanliness."

Mickle ³⁶³ later published the improved milk photographic sediment standards used in Connecticut, based on considerable work done by the

363. Mickle. 1932. Amer. J. Pub. Health 18, 926; Health Bull. Conn. State Dept. Health 42 (1928), 27; Amer. J. Pub. Health 19 (1929), 172-178; Internatl. Assoc., Dairy & Milk Insp. 18th Ann. Rept. 1929, 93-108.

Bureau of Laboratories of the Connecticut State Department of Health.

Results of any of the sediment tests which have been discussed apply only to invisible dirt. Other types of filth which might reach milk are not detected by the test. Committees of the International Association of Milk Sanitarians have shown the importance of the sample^{363a} and compared various testers.

Clarification and Filtration of Milk. Clarification consists of passing the milk through a machine to remove the dirt and foreign matter. Hammer³⁶⁴ quoted the following definition from *Hoard's Dairyman* in 1900: "Simply running the milk through a centrifugal separator for the purpose of removing the impurities, the spouts being so arranged that both empty into one vat, where the milk and cream are mixed before bottling." Severin and Budinoff³⁶⁵ observed an increased bacterial count, owing to clarification. Hammer also reported that plate counts of clarified milk were usually higher than plate counts of unclarified milk. These were said to be due to disintegration of clumps of bacterial cells, and not to contamination from clarified slime. This explanation is now generally accepted. A later report by Hammer and Hauser³⁶⁶ gave more data collected with a DeLaval clarifier, on the effect of clarification on the bacterial count of milk. Hammer noticed an increase in the number of bacteria, as in the former work. Fifty-two samples of milk with an initial count of under 100,000 were run through the clarifier. The great majority showed increases in counts, averaging 68 per cent. Clarification caused a decrease in tissue cell count, averaging 41 per cent. Armstrong³⁶⁷ stated that the clarifier removed 30 times as many bacteria as the filter. He believed that too many factors are involved for the bacteria-removing qualities to be dependable.

The practicability of the clarifier for the removal of visible dirt from milk caused Dahlberg and Marquardt³⁶⁸ to test the value of the filter. Visible insoluble sediment was completely removed by either filtration or clarification, but particles of sediment were revealed by microscopic examination in the filtered milk. They were absent in the clarified milk. Filtration seemed to have a variable effect on the bacterial counts, made by the plate, and direct microscopic methods. Clarification usually increased the number of colonies, as others have found (Baumgärtel and Struve³⁶⁹).

Lucas³⁷⁰ *et al.* experimented with samples of milk, ranging in volume from 2,000 to 5,000 lb., which were run through clarifiers and filters at varying temperatures to determine the merits of these machines.

Of the samples clarified at 29.4 to 33.3°C. (86 to 92°F.), 71 per cent showed a bacterial increase of 28.1 per cent, 10 per cent showed no increase, and 19 per cent showed an average decrease of 11.7 per cent. When clari-

fied at 12.8 to 18.3°C. (55 to 65°F.), 62 per cent of the samples showed an average increase of 25.9 per cent, 14 per cent showed no change, and 24 per cent had an average decrease of 12.2 per cent. Of the samples filtered at 29.4 to 32.2°C. (85 to 90°F.), 26 per cent showed an average increase in bacterial count of 24.4 per cent, nine per cent showed no increase, and 65 per cent showed an average decrease of 19.3 per cent. When filtered at 12.8 to 21.1°C. (55 to 70°F.) 27 per cent of the samples showed an average increase of 24.7 per cent, 19 per cent showed no change, and 54 per cent showed an average decrease of 29.3 per cent. The clarifier showed some selective action in removing peptonizers, but the filter had no such effect. Filtration had no influence on keeping quality, but clarification slightly reduced it. Neither process affected creaming ability to any great extent. Of the visible dirt, the clarifier removed 99 per cent at all temperatures, and the filter was almost as efficient, especially at the low temperatures. Filtering milk at temperatures of 32.2 to 46.1°C. (90 to 115°F.) required a change of filter cloth every two hours. Washing the cloth reduced its efficiency.

Hastings³⁷¹ believed that clarification was undesirable, since a milk dealer could clarify and sell dirty milk. Hastings stated that the clarifier did not improve the milk to the extent claimed by health authorities. Landis³⁷² took issue with Hastings, claiming that clarification was a desirable step in the milk plant, since it did remove dirt.

The advantages and disadvantages of clarification of milk were stated as follows by the Commission on Milk Standards:

In its favor are the following points:

- (a) It removes visible dirt.
- (b) It removes inflammatory products, including many of the causative germs.
- (c) It performs the work of the strainer, but in a much more efficient manner.

Against it are the following points:

- (a) It removes the visible dirt, but not all disease-producing bacteria, and hence misleads the consumer as to the real purity of the milk.
- (b) It does not remove urine or the soluble portions of feces; nevertheless, the milk appears clean.
- (c) It adds another process required in handling milk, complicating the situation.
- (d) It largely destroys the value of the dirt test, though not more so than good straining.
- (e) It breaks up clumps of bacteria and distributes them through the milk.
- (f) Exact nature of the material removed is not yet fully understood.

Grading of Milk Supplies. It is much easier to define high-quality milk than it is to determine whether it has been attained. The many methods

371. Hastings. 1917. *J. Amer. Med. Assoc.* 68, 899-901.

372. Landis. 1917. *Ibid.* 68, 1139.

which have been proposed for examination of milk are proof of this difficulty. Over the years that milk has been under scrutiny various systems of grading have been proposed, many of which were discarded soon after they were tried under practical conditions. Any answer to the question, "What is meant by quality in milk?"³⁷³ must satisfy the chemist, bacteriologist, nutritionist, and health official. The complexity of the problem is indicated by the fact that various systems of grading are used in larger cities and states. Practically all of them have had bacterial count standards as part of the definition for each grade. In some cases these bacterial count standards have carried the greater part of the load in milk control.

The United States Public Health Service Milk Ordinance and Code¹ which was also approved by the Bureau of Dairy Industry was prepared to encourage greater uniformity of milk-control practice in the United States. This ordinance and code probably embodies the best information at present available on milk-control legislation and is subject to change as improvements are developed. Many communities have adopted this code, which has raised milk quality wherever it is in force. The entire bulletin of 160 pages should be examined. Seven grades of milk are provided, as follows: (See also tabulation on page 340.)

Certified milk—raw. Certified milk raw is raw milk which conforms with the requirements of the American Association of Medical Milk Commissions in force at the time of production and is produced under the supervision of the Medical Milk Commission of the Medical Society of.....County, and of the State board of health or of the city or county health officer of.....

Grade A raw milk. Grade A raw milk is raw milk the average bacterial plate count of which as determined under sections 1 (S) and 6 of this ordinance does not exceed 50,000 per cubic centimeter, or the average direct microscopic count of which does not exceed 50,000 per cubic centimeter if clumps are counted or 200,000 per cubic centimeter if individual organisms are counted, or the average reduction time of which is not less than 8 hours: Provided, that if it is to be pasteurized the corresponding limits shall be 200,000 per cubic centimeter, 200,000 per cubic centimeter, 800,000 per cubic centimeter, and 6 hours, respectively; and which is produced upon dairy farms conforming with all of the following items of sanitation.

Grade A pasteurized milk. Grade A pasteurized milk is grade A raw milk, with such exceptions as are indicated if the milk is to be pasteurized, which has been pasteurized, cooled, and bottled in a milk plant conforming with all of the following items of sanitation and the average bacterial plate count of which at no time after pasteurization and until delivery exceeds 30,000 per cubic centimeter, as determined under sections 1 (S) and 6.

Grade B raw milk. Grade B raw milk is raw milk which violates the bacterial standard for grade A raw milk, provided that its average bacterial plate count, as determined under sections 1 (S) and 6, does not exceed 1,000,000 per cubic centimeter, or its average direct microscopic count does not exceed 1,000,000 per cubic centimeter if clumps are counted or over 4,000,000 per cubic centimeter if individual organisms are counted, or its average reduction time is not less than 3½ hours, and which complies with all other requirements for grade A raw milk except the provision for abortion testing of item 1r.

Grade B pasteurized milk. Grade B pasteurized milk is grade B raw milk which has been pasteurized, cooled, and bottled in a milk plant conforming with all of the requirements for grade A pasteurized milk, except the provision of lip-cover caps in item 20p, and the average bacterial plate count of which at no time after pasteurization

373. Harding *et al.* 1917. Ill. Agr. Expt. Sta. Circular 205.

and before delivery exceeds 50,000 per cubic centimeter, as determined under sections 1 (S) and 6.

Grade C raw milk. Grade C raw milk is raw milk which violates any of the requirements for grade B raw milk, and which shall be plainly labeled "cooking only."

Grade C pasteurized milk. Grade C pasteurized milk is pasteurized milk which does not meet the requirements of grade B pasteurized milk, and which shall be plainly labeled "cooking only."

Under this ordinance the health officer is instructed to announce the grades of all milk and milk products at least every six months. In some cities this is done every three months. This practice requires definite grading periods which are discussed as follows in the ordinance:

T. Grading period. The grading period shall be such period of time as the health officer may designate within which grades shall be determined for all milk and milk products, provided that the grading period shall in no case exceed 6 months.

Wide experience in the operation of this ordinance has indicated that it is undesirable to make the grading period shorter than 3 months. This is because most towns find it difficult to make inspections and analyses often enough to permit a shorter grading period.

On the other hand, the ordinance does not permit grading periods longer than 6 months. Experience has indicated that grading periods longer than 6 months result in inadequate supervision of the supply.

A grading period of 6 months does not imply an excessive enforcement cost. As a matter of fact, many of the cities enforcing this ordinance are grading every 3 months without prohibitive expense.

Examination of samples of milk and milk products during each grading period is provided as follows:

SEC. 6. *The examination of milk and milk products.* During each grading period at least four samples of milk and cream from each dairy farm and each milk plant shall be taken on separate days and examined by the health officer. Samples of other milk products may be taken and examined by the health officer as often as he deems necessary. Samples of milk and milk products from stores, cafes, soda fountains, restaurants, and other places where milk or milk products are sold shall be examined as often as the health officer may require. Bacterial plate counts and direct microscopic counts shall be made in conformity with the latest standard methods recommended by the American Public Health Association. Examinations may include such other chemical and physical determinations as the health officer may deem necessary for the detection of adulteration, these examinations to be made in accordance with the latest standard methods of the American Public Health Association and the Association of Official Agricultural Chemists. Bacterial plate count, direct microscopic count, reductase test, and cooling temperature results shall be given to the producer or distributor concerned as soon as determined if said results fall without the limits prescribed for the grade then held. Samples may be taken by the health officer at any time prior to the final delivery of the milk or milk products.

During the grading period the bacteriological condition of the milk is also determined by different methods:

S. Average bacterial plate count, direct microscopic count, reduction time, and cooling temperature. Average bacterial plate count shall be taken to mean the logarithmic average of the bacterial plate counts of the last four consecutive samples, taken upon separate days, irrespective of periodic grade announcements. Average direct microscopic count shall be taken to mean the logarithmic average of the direct microscopic counts of the last four consecutive samples, taken upon separate days, irrespective of periodic grade announcements. Average reduction time shall be taken to mean the arithmetic average of the reduction times of the last four consecutive samples, taken

upon separate days, irrespective of periodic grade announcements. Average cooling temperature shall be taken to mean the arithmetic average of the temperatures of the last four consecutive samples, taken upon separate days, irrespective of periodic grade announcements.

Experience in cities which have adopted this ordinance has been satisfactory.³⁷⁴ One cannot help but wonder whether the practice in New York City, discussed at the end of this chapter, is not a much better one.

Bulmer³⁷⁵ believed that the U. S. Public Health Service Ordinance and Code was inadequate in so many ways that it failed where it was supposed to do good. While the ordinance contained a maze of detail as to how milk should be pasteurized, it did not consider safeguards for the product after pasteurization. Bulmer also pointed out that it provided for a multiplicity of grades. A vendor is allowed to have in his possession, for instance, grades A, B, and C of both raw and pasteurized milk at the same time. Sale of milks of certain grades would be controlled with difficulty under such conditions.

While several hundred small cities have adopted the standard ordinance, only a small number indeed of the large one have. Where it has been adopted by the latter, it has been profoundly modified. It is also very doubtful to the author of this book whether the average small community which glibly adopts this ordinance can afford the corps of inspectors, chemists, and bacteriologists which would be necessary to make it work. Any community which adopts such an ordinance and cannot afford to hire the experienced help which would be needed to enforce it, is living under a false security as far as its milk supply is concerned.

Another proposal for grading milk without use of bacterial count standards was made by Harding *et al.*³⁷³ They recognized three grades of milk, special milk, table milk, and cooking milk. These were defined in terms of four elements of quality, food values, healthfulness, cleanliness, and keeping quality, as follows:

Grade	Element of quality	Degree of excellency
Special milk	Food value	Fat content as stated on package
	Healthfulness	Medical supervision of health of men and animals, or proper pasteurization
	Cleanliness	Sediment, not more than a trace
	Keeping quality	Excellent
Table milk	Food value	Fat content as stated on package
	Healthfulness	Properly pasteurized
	Cleanliness	Sediment, no more than a small amount
	Keeping quality	Good
Cooking milk	Food value	Fat content as stated on package
	Healthfulness	Boiled
	Cleanliness	May not be sufficient for table grade
	Keeping quality	May not be sufficient for table grade

374. Fuchs and Kroeze. 1930. Pub. Health Repts. 45, 1412-1421.

375. Bulmer. 1938. J. Milk Tech. 1, 10-13.

This proposal includes about all that should be involved in a definition of good milk. Park³⁷⁶ took issue with some of the conclusions reached by Harding and his colleagues, because they were interested more in the farm than the infant. Park believed that the number of bacteria in milk should not be ignored. Harding and his colleagues believed that other things should be considered.

The problem to settle with respect to bacterial count standards is, What do they mean? Is a milk supply with a bacterial plate count of 75,000 per ml. more dangerous than one averaging 30,000 per ml.? Is pasteurized milk more healthful if it results from heating milk having a plate count of 200,000 per ml. than if it had a plate count of 1,000,000 per ml.? Sherman³⁷⁷ has stated that he could see no reason for any difference in healthfulness of pasteurized milk made from raw milks of varied bacterial contents below 750,000 per ml. He further stated that there was no reason to fear "bacterial metabolic products" after pasteurization. Presumably he had in mind products which might result from disintegration of dead bacterial cells.

The present U. S. Public Health Service Standard Milk Ordinance and Code¹ provides for seven different grades of milk, all but three of which have bacterial count standards. Those in which no limit was established for bacterial content are Grade C raw and Grade C pasteurized. The advisory board has defended itself by stating:

"Public-health reason. It is widely accepted that the bacterial count of milk is an index of the sanitary quality of milk. A high count does not necessarily mean that disease organisms are present, and a low count does not necessarily mean that disease organisms are absent; but a high bacterial count does mean that the milk has either come from diseased udders, has been milked or handled under undesirable conditions, or has been kept warm enough to permit bacterial growth. This means, in the first two cases, that the chances of infection have been increased, and, in the last case, that any infection which has reached the milk has been permitted to grow to more dangerous proportions. In general, therefore, a high count means a greater likelihood of disease transmission.

"On the other hand, a wrong interpretation of the significance of low bacterial counts should be avoided, since low-count milk may be secured from tuberculous cows, may have been handled by typhoid carriers, and may even have been handled under moderately unclean conditions."

New York City established milk grading in 1911 and recognized several grades. Since differences in Grade A and Grade B pasteurized milk had become of so little sanitary significance, New York City adopted a regulation in September, 1940,³⁷⁸ for a single grade designated as "Approved." Distribution of certified milk was not affected. According to one authority standards for this new grade of milk are higher than those for former Grade B, which comprised about 87 per cent of the total milk supply, but lower than former Grade A, which was purchased by about 12 per cent of local citizens. The new standards are as follows:

376. Park. 1918. J. Amer. Med. Assoc. 70, 720.

377. Sherman. 1939. J. Milk Tech 3, 41.

378. Amer. J. Pub. Health 30 (1940), 1111-1112.

	Maximum number of bacteria per cubic centimeter
Approved Milk—after pasteurization and when delivered to consumer.....	30,000
Approved cream—after pasteurization and when delivered to consumer..	100,000
Approved Milk—when produced in New York City or before pasteuriza- tion at country plant.....	150,000
Approved Milk—before pasteurization after shipment from country plant.....	400,000
Approved Cream—before pasteurization at country plant.....	250,000
Approved Cream—before pasteurization after shipment from country plant.....	500,000
Certified Milk—pasteurized	500
Certified Milk—raw	10,000
Milk must contain at least 3.3 per cent butterfat and 11.5 per cent solids.	
Light cream must contain at least 25 per cent butterfat.	
Heavy cream must contain at least 36 per cent butterfat.	

Rice and Pincus³⁷⁹ justified this change in grading of milk for America's largest city. They stated that it was wise to discontinue grades of milk when the health significance of minor differences between grades had been illusory or non existent. This action caused much discussion. The question was asked whether continuance of specifications for Grade A milk were justified in view of the fact that such milk had to sell at higher price. Answers to such questions must rest on results secured in comparison of milks of different grades. Fortunately, in this case such a comparison between Grades A and B milk in New York City were made by Isaacs and Nussbaum.³⁸⁰ Grade A milk was found to be a more uniform and cleaner product than Grade B milk.

Following New York City the New York State Public Health Council voted to provide only one grade of pasteurized milk for the entire state after April 1, 1941, to be known as "Grade A Pasteurized." The bacteria content limit after pasteurization remains at 30,000 per ml. Others were stipulated.³⁸¹

CHAPTER 6

BACTERIOLOGICAL ANALYSIS OF MILK

In no other place in food technology has bacteriology played a role of greater importance than in the milk and milk products industries. Its methods and technics are used to appraise the conditions under which milk is produced and handled as well as to control the quality of various products made from it. Healthfulness and keeping quality are assured by constant vigilance of bacteriologists.

Methods for the laboratory examination of milk as well as other dairy products are embodied in *Standard Methods for the Examination of Dairy Products*, published by the American Public Health Association. These procedures are revised every five years or so. Other associations have, at times, published methods of analysis. These make available to the bacteriologist approved technic for determining the sanitary quality of milk. Another useful discussion of methods and apparatus is that by Robertson and Schacht.¹

THE "BACTERIAL COUNT" OF MILK

Quality of milk for many years has been defined in terms of its bacterial count. While such "bacterial counts" were once believed to reflect quality, they have lost much of their significance today, for reasons which have been well stated by Wilson.² In order to avoid some of the criticism of "bacterial counts" new expressions have been proposed which, while perhaps somewhat more accurate, do not entirely correct the evil. Breed³ believed the term "count" to be a misnomer and stated that no one had ever counted the bacteria in milk in the same manner that the number of people in a room had been counted. He looked upon the count as more of an estimate and used this term in place of "counts." His proposal was never widely adopted, for *Standard Methods for the Examination of Dairy Products* uses the words "count" and "counting," as well as "estimation of the count." Breed then mentioned some errors involved in using this technic, some of which are mentioned below. He also mentioned the fact that bacterial counts can and are frequently misused and that there is a general tendency to assume an accuracy for them which they do not possess.

The plate count has been analyzed from many angles by different investigators. One of the most recent, by Wilson² states:

The plate count is severely criticized. Ostensibly it measures the number of bacteria in milk, but in fact it does not. On account of the difference between various species of bacteria in their nutritional, respiratory, and temperature requirements, on account of the fact that many organisms may be dead, and most important of all on account of the gross irregularity in the distribution and clumping of the organisms in the milk, the plate count merely registers the number of bacterial units capable of mul-

3. Breed, 1927. Amer. J. Pub. Health 17, 604-606; N. Y. Agr. Expt. Sta. Bull. 567.

tipling under the particular conditions selected. Since the average number of bacteria per clump is variable from one milk to another, and from time to time in the same milk, and since these clumps may disintegrate to a quite uncontrollable extent during the process of dilution, it follows that the figures yielded by the plate count are arbitrary, not strictly comparable from milk to milk, merely approximate and have no real significance."

Wilson also pointed out that the technic is difficult to standardize and that the experimental error is large; an allowance of ± 90 per cent may have to be made. Rogers,⁴ at a much earlier date, cautioned against using the plate count as a delicate criterion of quality. He stated that it was impossible to distinguish between original contamination and the unknown factor of bacterial multiplication.

Kilbourne⁵ emphasized the danger in using the bacterial count as the only means of controlling a milk supply. He sent samples from the same lot of milk to different laboratories, and received results of analysis which were surprising. The variation was so great that, on first thought, one would be tempted to abandon the count entirely. Kilbourne, however, advised the use of other data along with the count. Tiedeman and Hohl⁶ called attention to many of the shortcomings of the plate count and called on health officers to demand a revision or to discontinue its use. They further called attention to the fact that health officers have largely been forced to turn to sanitary inspections to determine the safety of milk. With respect to pasteurized milk, other methods have been introduced.

A few bacteriologists have supported the bacterial count. Probably their opinions would be accepted today largely in relation to the times when they were held. In earlier days, many more bacteria were found in milk than are generally found today. This is brought out by the standards which were once adopted by cities.

Hastings,⁷ at the University of Wisconsin, discussed the bacteriological analysis of milk as follows:

The value of bacteriological analyses in the dairy industry has been established beyond all question. From the viewpoints of the producer, the distributor, and the ultimate consumer of milk, whether the home or the dairy manufacturer, the bacteriological examination of milk gives information concerning the product which can be obtained in no other way. The further extension of such work is certain to be to the advantage of all concerned.

Conn⁸ has well stated the question. *"The bacterial analysis of milk is not to be taken as indicating in itself a condition of safety or a condition of danger, but only as a warning. Good, clean, fresh milk will have a low bacterial count, and a high bacterial count means dirt, age, disease, or temperature. A high bacterial count is, therefore, a danger signal, and justifies the health officer in putting a source with persistently high bacterial count among the class of unwholesome milk."*

Both of these investigators spoke when milk harbored many bacteria. When Park and Holt⁹ did their well-known work on the relation of the bacterial content of milk to infant health in New York City this was also the case.

8. Conn. 1916. Milk Dealer 6, 50-55.

9. Park and Holt. 1903. Med. News 83, 1066-78.

Park¹⁰ found that the bacterial count checked quite well with the health of children fed milks with different contents of bacteria as well as the temperatures at which the milk was stored. He found that during the coldest weather the milk of New York City averaged 250,000 bacteria per ml. and during hot weather 5,000,000. Investigation showed that the milk in other large cities was in about the same condition. Attention was called to the fact that children in cities sicken on the milk in summer, but, as a rule, they improved when they were fed milk which was sterile or had few bacteria. Any intelligent farmer, with cleanliness and low temperatures, can produce milk with a count less than 100,000 bacteria per ml. Modern methods of milk production yield milk with far fewer bacteria than this.

A similar study of the effect of different grades of milk on infants was reported by Park and Holt. The study covered infant feeding in tenement houses during winter and summer. The observations were made by physicians. Bacteriological studies were made on the milk, and 239 varieties of bacteria were isolated. Without reviewing the experiments and data in great detail, we may state that the quality of the milk influenced the amount of illness and also the mortality. Those who received cheap store milk showed material ill effects.

Those who have supported the bacterial count have done so on the grounds that it reflects the conditions under which milk is produced. Opponents have pointed out that the true nature of foreign matter is not indicated. Harding,¹¹ for instance, stated that fairly large amounts of cow manure could be present in milk, without increasing the bacterial count to any marked extent. Allen¹² and Taylor,¹³ however, did not agree with Harding.

One difficulty in using the plate count as a criterion of milk quality has been count standards. Savage¹⁴ found the greatest objection here. While formerly there was little agreement among various city milk ordinances as to the permissible number of bacteria in milk, today they are in better agreement. An acceptable standard today is probably around 30,000 bacteria per milliliter, the count which appears in the United States Standard Milk Ordinance and Code.¹⁵ Many cities have adopted this standard.

While plate-count standards have helped in the fields of milk sanitation and control, there is an increasing tendency to give them an importance which they probably do not deserve. If new methods for determining plate counts, such as a new plating medium and incubation temperatures which give much greater numbers of bacteria, can be accepted by official groups without changing standards which have accompanied the older technics which were replaced, something is wrong in milk control. How can the situation be explained to producers? Parker¹⁶ in discussing this question,

suggested that it is time to analyze some efforts to improve milk, such as the continual demand on the part of a few dairy bacteriologists that plate-count standards be lowered. It is doubtful whether milk produced from healthy cows under adequate sanitary inspection is any more sanitary if it contains 15,000 harmless bacteria per ml. than if it contains 30,000 harmless bacteria. The great question is whether milk is clean and safe. Parker suggested that some attention should be given to qualitative methods in milk analysis—that the type of bacteria has some weight. If the present tendency to force lower and lower plate counts is not controlled, the public is going to be asked to pay for much effort in milk production which makes no contribution to better milk. Perhaps it was that fact which caused health authorities in New York City to provide for just one grade of milk, “Approved Milk.”

Reporting of Bacterial Counts. *Standard Methods for the Analysis of Dairy Products* gives specific directions for reporting counts. While this advice was pointed mainly at milk, it may also be applied to other foods. Since the count is only an estimate of the bacterial population, it is recommended that the expression “number of bacteria per c.c.” not be used. When the standard technic is used they recommend that the expression “Standard Plate Count, 20,000 per ml.” be used rather than “20,000 per c.c.” Wilson,² in his comprehensive analysis of the problems involved in milk analysis, also stated that care should be used in expressing results of use of the standard agar plate. To report the results as “the number of bacteria per ml.” is wrong. The results should be reported as “the number of colonies developing per ml.” or “the plate count per ml.” should be used. Publication of counts from individual samples is also frowned upon. The United States Public Health Service Milk Ordinance and Code¹⁵ recommends a logarithmic average of four samples as the count that shall be used.

The practice of publishing counts in newspapers is open to serious criticism. The public is not in position to properly interpret them (Prouty¹⁷) or even to know what the count means.

Limits of Error in Plate Count of Milk. These are due to many different factors, some of which are discussed below. To reduce them to a minimum bacteriologists have prepared “standard procedures” which have not eliminated all variations in counts. Some of them cannot be eliminated. Results of several comparative studies between laboratories have revealed some of the places where improvements could be made. Similar studies within one laboratory have revealed great variations because of the human element. Results of such comparative investigations must be interpreted with considerable care. In 1914, four laboratories in New York City decided to conduct a comparative test by which some of the factors leading to errors could be corrected. Conn acted as referee.¹⁸ On certain dates he distributed to the laboratories a series of samples of milk, sometimes as many as 40 and as few as 15. He found that individual analyses, under the

17. Prouty. 1941. *J. Milk Tech.* 4, 32-34.

18. Conn. 1915. *Public Health Repts.* 30, No. 33.

best conditions, were subject to considerable variation, so that no single individual count could be relied on. An average of two or more plates should be demanded. Conn did point out that if standard procedures were used more consistent counts could be secured in different laboratories.

Hatfield¹⁹ reported results of a similar comparative study of the methods of milk analysis made in four New York City laboratories. The greatest variations occurred in counts secured by plating raw milks. The studies were apparently not very extended, and involved mainly counts from plates. When the nature of the test was taken into account, and when the plates were not too highly seeded, Hatfield believed that counts made from the various dilutions could be expected to agree quite closely. Breed and Stocking,²⁰ in a similar comparative study, submitted samples of milk to several different analysts, working in laboratories situated within 50 miles of each other. The details of the study cannot be reported in this place. However, it was reported "that skilled analysts, using proper technique, ordinarily obtain reasonably accurate estimates of the number of living bacteria in cubic centimeter samples of milk by plate method *provided* the milk contains isolated organisms of a type capable of growth on agar under the conditions maintained." This is an interesting reservation, for different samples of milk may not have such bacteria or they may be present in different concentrations.

Slack²¹ has also reported a study of results from different laboratories about and in Boston. Nine laboratories co-operated. The composition and reaction of the medium was found to be a factor of importance. After a conference of the workers, they decided to follow a uniform procedure. An important cause of variation in results was the reaction and composition of the medium. Quite wide variations in results were secured.

The Connecticut State Board of Public Health²² also reported results of a co-operative study of duplicate milk samples plated simultaneously in nine laboratories. Considerable care was used in the preparation of the samples in order that this part of the work could not influence the results. Incubator temperatures were taken at the level of the plates in each laboratory twice daily during the test. Other details such as pH of media and occurrence of pin-point colonies were noted.

Co-operative investigations have been carried out by the New York State Department of Public Health and the Department of Agriculture and Markets.²³ The former had 80 sets of 10 identical samples of milk analyzed by 78 technicians in 74 laboratories. They found the results secured in the various laboratories to be in close agreement on normal low-count raw milk, on abnormal raw milk; pasteurized milk, however, showed variations. Further standardization of technic was recommended. The department conducted counting contests from which it was concluded that personal

equation offered the greatest source of error. Some of the causes of error were (1) failure to know what to count, (2) failure to see the colonies, and (3) carelessness. More attention was focussed on the nature of the counting device than had been given it before. Wilson² reported about the same opinions.

In view of results reported in the literature by Conn¹⁸ and Schacht and Robertson,²⁴ Wilson² made a few observations on the problem. His discussion with tables should be studied for the full details. They are quite instructive. In one experiment 12 plates were counted by 12 observers under the same conditions. The observers were individuals who had had some experience in bacteriological work. Several errors in counting were revealed. Personal bias and faulty counting apparatus were mentioned as especially important. Milk analysts should read Wilson's discussion.

The problem has been studied from another angle. Several investigations have been carried out to determine how nearly the counts secured on a long series of plates made as rapidly as possible from a sample of milk, would agree. Results of such experiments must be interpreted with great care. Considerable time is consumed in making such a series and the plates made at the beginning and end may be quite different. The reasons are obvious.

Wright and Thornton²⁵ made 2,330 counts of milk plates poured in duplicate series, 100 plates to the series, in order to determine how accurate plate counts could be. They reached the conclusion that quantitative plate counts were no more accurate than other methods available for judging the quality of milk. These investigators diluted 10 ml. of milk in 990 ml. of salt solution, used 10 ml. of agar in each Petri dish, and incubated the dishes in piles only three dishes deep. Great variation was found. Mudge and Lawler,²⁶ after a statistical analysis of a large number of plate counts, stated that statistical analyses were of no value. Albus²⁷ analyzed some of the difficulties which enter the making of a large series of plate counts as were made by Wright and Thornton, for instance. He called attention to the time factor that must be taken into account, for no matter how experienced the technician is, he cannot make 100 plates in the short time required to entirely overlook the fact that the bacteria may multiply in the dilution bottles. Consequently, Albus believed that the results of such experiments should be interpreted with the greatest care. Mudge and Lawler confirmed these opinions. They observed a significant rise in the number of colonies upon allowing the milk-water dilutions to stand. They stated that the dilution bottle was a hitherto unsuspected factor for variation in counts secured by the agar plate method.

Malcolm,²⁸ in similar work, used a simplified plating medium and a large number of parallel plates. It was shown that in a very high proportion of samples the plating method is unreliable if only one or two plates

are poured for each dilution. It is suggested that in routine examination of unpasteurized milk the 1-10 dilution bottle and plates be omitted, and the 1-100 dilution, prepared by adding one ml. of the specimen to 99 ml. of sterile water be used. The 1-1,000 dilution bottle should be omitted, the 1-1,000 dilution plates being prepared directly from the 1-100 dilution bottle, using .1 ml. of inoculum measured by a special pipette. Five parallel plates should be poured for the 1-100 dilution and at least two for the 1-1,000 dilution. To obtain fairly accurate estimates, when the counts are in the neighborhood of 100,000 organisms per ml., at least five plates should be used for the 1-1,000 dilution.

One of the most thought-provoking discussions relating to plate-count problems is that by Wilson.² It should be examined by all who are analyzing the merits of plate counts of milk and other foods.

The Spreading Colony. These are troublesome in most milk-control laboratories. They render plate counts inaccurate or make it entirely impossible to secure them. Schacht²⁹ recognized three types of colonies which might be counted differently by different analysts. Two of them were the typical spreader while the third was the long chain of colonies. It was recommended that masses of spreading colonies be counted as units and not as individuals. The generally accepted explanation of spreaders is that they are caused by excessive moisture. The porcelain cover for the Petri dish was introduced to take up such moisture and prevent spreaders. Boerner and Robinson³⁰ stated that the condition of the surface of the agar influenced appearance of spreaders. They found that use of less than 10 ml. of agar medium in the dish restricted spreaders. Schacht found a relation between the amount of agar used in the medium and spreaders. One essential factor in control of spreaders is thorough mixing of the contents of the plate.

Factors Influencing Plate Counts of Milk. Arbitrary conditions have been established for determining the number of bacteria in milk by the agar-plate method. Unless these are strictly followed, variable results will be secured.

(a) *Media for Plate Counts.* Many different media have been used, the main characteristic of which was that they permitted more bacteria to develop. The earlier editions of *Standard Methods of Milk Analysis* specified plain nutrient agar as the plating medium. While it probably did not reveal all of the bacteria which were present in the milk, it yielded results which were the basis of real progress in milk sanitation.

Standard Methods for the Examination of Dairy Products, 1939 edition, provided for a new medium with a quite different composition from the old one. It is known as tryptone glucose-skim milk agar medium in the literature but is designated as nutrient agar in the standard methods just mentioned. This medium gives higher counts. That is about the only advantage it has. It is more complicated in composition and has the disadvantage that a material, skim milk, of somewhat indefinite nature is added. If, as Wilson² has stated, the plate count at best is subject to error of ± 90 per cent, the advantages of the new medium are not always apparent. Myers and Pence³¹ eliminated the skim milk from their formula because it exerted a negligible effect on the count

31. Myers and Pence. 1941. J. Milk Tech 4, 18-25.

and was merely troublesome. Furthermore it made the medium more turbid and occasionally caused a precipitate to be formed.

Van Horn³² made media with Witte's peptone, Difco beef extract, and Liebig's meat extract. Comparative counts on these media gave more than three times as many on the media containing Difco beef extract, with pasteurized milk. With raw milk, however, the counts were only slightly higher.

A similar, but perhaps more comprehensive investigation of this subject was made by Supplee, Whiting, and Downs.³³ They compared three media and three incubation temperatures by making parallel counts on 100 samples of milk collected in Ithaca. The data are summarized in Table 2.

Attention was also given to the location of the Petri dishes in the incubator. They found that the lowest counts and the greatest variability were secured on plates which were placed in the interior of solid blocks of dishes. When the plates were exposed to warm circulating air, relatively high and uniform counts were secured.

Norton and Seymour³⁴ compared five different media using raw and pasteurized milk. Veal infusion media ranked first and meat extract and two dehydrated media second. Ayers and Mudge's³⁵ milk powder medium was less satisfactory. Norton and Seymour concluded that standard agar medium, dehydrated nutrient agar, and dehydrated peptonized milk agar were equally satisfactory.

The conclusions mentioned above indicate that standard technic should be strictly adhered to. Even slight departures will yield varying results. On this basis, we may explain some of the controversial situations which have arisen in the past.

TABLE 2

Influence of Medium and Incubation Method on Bacterial Counts of Market Milk
(After Supplee, et al., 1921)

Incubation temperature Incubation time			Relative counts		
			Plain agar 1%	Lactose agar 1%	Dextrose agar
C.	F.	Hours			
37°	98.6°	48	100.0	175.3	444.9
30°	86°	120	519.1	453.5	778.6
20°	68°	120	411.4	498.5	664.8

Lactose Agar. Milk sugar has been found by many to cause higher counts when added to plain agar. Sherman³⁶ reported that lactose agar gave 43 per cent more colonies than plain agar. Not only were increased counts secured, but the colonies were also larger which made counting easier. The average diameter of the 10 largest colonies on plates from one culture of *Lactobacillus lactis acidii* was 64 μ on plain agar and 614 μ on lactose agar. Sherman also found lactose agar to be of value for differentiating the type of organisms on the plates.

Milk Powder Agar. Ayers and Mudge³⁵ recommended the use of milk powder agar for accurate determination of bacteria in milk. The total counts were much higher than when meat-extract-agar was used. Borck³⁷ also found milk agar to be superior to meat extract agar. Parker and Byers³⁸ compared the standard agar medium for milk analysis and Ayers' milk powder agar. They found that the colonies on the milk powder agar were larger and more easily counted. With raw milk containing less than 10,000 bacteria per ml. there was no difference but when more than 50,000 bacteria

were present, higher counts were secured. With pasteurized milk higher counts were secured with the milk agar. Zoller and Eaton³⁹ modified Ayers and Mudge's milk powder agar. The counts on milk powder agar were always higher than on the standard agar. In a comprehensive comparison of different agar media Supplee and Flanigan⁴⁰ plated 100 samples of milk in seven different agars and incubated the plates for 48 hours at 37°C. (98.6°F.). Assuming that the average of all counts obtained on standard agar was 100 per cent, each of the averages from the other media showed the following relationships to the standard extract agar: previous standard infusion agar, 124.4 per cent; Bacto dehydrated agar, 114.7 per cent; Bacto dehydrated agar with milk, 153.2 per cent; dehydrated milk agar as prepared by the research department of a dry milk company, 167.6 per cent; Ayers' milk agar prepared with spray process milk powder, 170.9 per cent; Ayers' milk agar prepared with Just hot cylinder process milk powder, 177.2 per cent.

Skimmed Milk Agar. It is logical that sterile milk be added to the medium when organisms in milk are to be counted. A certain amount of milk always reaches the plates especially in low dilutions. Barkworth⁴¹ analyzed three sets of experimental observations, viz., his own, those of Thomas,⁴² and those of Provan, Dudley, and Thomas.⁴³ His tables show that use of one per cent milk agar gives a "significant" increase in colony numbers for both raw milk and pasteurized milk and this at all levels of count. With .01 and .001 dilutions of the pasteurized milk organisms which will not grow on standard agar showed marked growth on milk agar. Milk agar gives better colony growth and so aids rapid and accurate counting.

Studies at the National Institute for Research in Dairying, England, by Hiscox, Hoy, Lomax, and Mattick⁴⁴ showed that neither lactose nor other sugars tested, casein peptone, or yeast extract could satisfactorily replace milk as a means of correcting the discrepancies often observed between plate counts of the 1-100 and the 1-1,000 dilutions of milk on standard agar.

Thomas⁴² also found that addition of one per cent skim milk to standard agar increased the colony count by ratios of 1.9 and 4.8 in samples of raw and pasteurized milks, respectively. With mastitis milk, parasitic streptococci were able to grow in pinpoint colonies on milk agar. Milk agar was much more suitable than yeast dextrose agar for the growth of thermophilic bacteria at 12.8°C. (55°F.) and particularly at 17.2°C. (63°F.).

Based on data obtained on approximately 760 samples of milk taken from the milk supply of 250 dealers representing winter, spring, and summer conditions, Safford and Stark⁴⁵ found that fermentable carbohydrates and other milk constituents in skim milk agar made a desirable medium to use in the routine control of market milk and other dairy products.

On 618 samples of pasteurized milk the skim milk agar counts averaged two to four times as large as the corresponding counts on standard agar. The counts on 137 samples of raw milk were only slightly larger. The colonies on the skim milk agar were much larger and could be counted with greater ease and rapidity than those on standard agar. The slight opacity of the medium prevented glare when artificial lighting devices were used. Acid-producing and protein-digesting types of bacteria could be differentiated on this medium, and it supported growth of the bacteria responsible for mastitis. The medium was simple and easy to make, and no more expensive than the standard agar.

Continuing this line of investigation, Safford and Stark⁴⁵ compared the bacterial counts of 190 samples of pasteurized milk plated on standard agar and on tryptone-glucose agar plus one-half and two per cent skim milk. Using arithmetical averages of

percentage differences, the one-half per cent skim milk agar counts were 180 per cent higher and the two per cent skim milk agar counts 215 per cent higher than the corresponding standard agar counts. The two per cent skim milk agar also possessed superior differential value for bacterial types, which was considered especially advantageous in the bacterial examination of such products as butter, cheese, and starters.

Tryptone Glucose Skimmed Milk Agar. This is the standard plating medium in *Standard Methods for the Examination of Dairy Products*, eighth edition, 1936. Its adoption was mainly at the instance of Breed and his coworkers who reported a much higher count with it than was secured with the old standard agar medium. Bowers and Hucker⁴⁶ examined a large number of raw milk and pasteurized milk samples and compared the counts given after two days' incubation at 31°C.(87.8°F.) with standard agar (peptone-beef extract agar), tryptone-glucose agar, and tryptone glucose-skim milk agar. Compared with standard agar, tryptone-glucose agar increased the colony count in raw milk by approximately 34 per cent and in the pasteurized milk by 47 per cent. The addition of skim milk increased the counts by approximately four per cent for raw and eight per cent for pasteurized milk. The use of neo-peptone instead of tryptone did not increase the colony count nearly to the same extent. Bowers and Hucker recommended the use of tryptone-glucose agar, and thought the addition of skim milk to be unimportant. Bowers and Hucker assumed that their medium was an improvement because it gave a higher count than the standard plating medium then used. This may not be necessarily true. The best medium is that which indicates most accurately the sanitary condition of milk.

Tryptone glucose-skim milk agar was also compared with standard agar by Bradfield⁴⁷ at incubation temperatures of 32°C.(89.6°F.) and 37°C.(98.6°F.) using several types of milk. He also showed that higher counts were secured with the new medium. This was confirmed by Frayer⁴⁸ at the same station. He found that the new medium and lower incubation temperatures produced more luxuriant colonies in greater numbers. Also, on account of the opacity, visibility, especially of the smaller colonies, was increased. Yale,⁴⁹ working in the same laboratory in which the new medium was developed, confirmed what has been said above with respect to increased counts. He also apparently believed that a medium was better if it permitted more bacteria to grow on the plates. Whether the new medium and incubation temperature better reflected production conditions was not discussed. Abele,⁵⁰ Abele and Damon,⁵¹ Phelan,⁵² Lind,⁵³ Dixon,⁵⁴ and Marcus⁵⁵ all reported higher counts with tryptone glucose-skim milk agar than with the standard nutrient agar. Parker⁵⁶ has questioned the mathematical interpretations which Abele made from his data.

Powers⁵⁷ believed that a thorough comparison of glucose tryptone agar and plain nutrient agar should have been made before official adoption of the former. Seventeen laboratories in 10 states co-operated in making some 25,150 plate counts over a 12-weeks period. A statistical analysis of these plates was reported by Kelly.⁵⁸ Lowering of the temperature of incubation was said to be the greatest single factor in increasing plate counts irrespective of the culture medium used. In a later paper Kelly⁵⁸ reported that standard agar at 32°C. gives more uniform results between plants than tryptone agar at either 37°C. or 32°C. Grade A pasteurized milk seemed to be one of the few exceptions to this. There was greater variation in the results from different laboratories on the same sample of milk with the same medium than there was between

the results in the same laboratory using different media and temperatures. It would seem that laboratory procedures need to be standardized and that greater care to control conditions be exercised if satisfactory results are to be obtained.

Yale and Hickey⁵⁹ subjected 112 samples of ice cream to analysis with tryptone agar and the then standard nutrient plain agar. The results favored the former.

When tryptone glucose-skim milk agar was adopted as the standard medium, it was suggested in some quarters that new standards would be needed. This is probably not necessary. Abele stated that the average plate-count limits now fixed for milk and frozen desserts by ordinances and regulations need not be raised in order to avoid chaos in grades of milk and milk products. This virtually means that the plate count standard is suddenly lowered. If no change in plate count standards was needed when a medium was adopted which permitted many more bacteria to be counted, the old standards were wrong and too lenient. Perhaps, this again shows the weakness of plate counts and standards which are used with them in milk control.

Apparently introduction of the new medium will not interfere with development of pyogenic streptococci and organisms in milk from cows with mastitis. In one case Foltz and Bushnell⁶⁰ found more colonies on the new medium than when blood agar was used for examining milk from an animal responsible for an outbreak of septic sore throat.

(b) *Location of Plates in the Incubator.* Supplee, Whiting, and Downs³³ studied this because they believed that differences in temperature would result from piling plates in the smaller types of incubator. They found that when the plates were placed in the incubator so that there was free circulation of air, the counts were uniform. Every location in all incubators cannot be maintained at exactly the same temperature. Those plates which are near the source of heat may be hotter than those which are at a distance. Such conditions probably do not hold for the large incubators which are constructed in a small room. Where small incubators are used, those with water jackets are recommended since they permit more even heating of the incubation chamber. Wilson recommended such an incubator in his suggested technic for plate counting.

(c) *Temperature of Incubation.* Variations in the temperature at different places in incubators have been observed for a long time. These have been studied for their effect on plate counts. Widely divergent temperatures of incubation have also been studied. Breed and Pederson⁶¹ tested incubators made to operate at 37°C.(98.6°F.) by packing them full of agar plates all prepared from a single sample of milk. Variations in counts were observed and attributed to temperature differences. They might have been and probably were due to the variations which are always observed when many plates are made from the same sample of milk. Prucha⁶² showed this in some of his work on the sources of bacteria in milk. He made 100 plates from the same sample of milk. The lowest count was 110 and the highest 170. Sixty-two of the plates showed between 131 and 150 colonies. Breed and Pederson in one case prepared 800 plates from one sample of milk and apparently assumed that the counts should agree closely. Robertson⁶³ compared the standard temperature 37°C.(98.6°F.) with 21°C.(69.8°C.). At 37°C. for 48 hours, counts were secured which were accurate in only one-third of the cases. When the incubation temperature was increased to five days at 21°C., better correlations were secured. Robertson believed that another temperature than 37°C. should be adopted for standard methods. Supplee, Whiting, and Downs³² studied incubation temperatures of 37°C., 30°C.(86°F.), and 20°C.(68°F.). Higher counts were secured at 30°C. and 20°C.

Later Pederson and Yale⁶⁴ carried out a similar investigation. Seventy-eight samples of dairy products were examined by making 75 duplicate plates from each sample. They were incubated at 21, 25, 30, 32, 35, 37, 39, 45, and 55°C. In general the results

59. Yale and Hickey. 1937. *J. Dairy Sci.* 20, 755-760.

showed that the counts increased with temperature up to 32°C., and decreased as the temperature went above 32°C. The count secured at 37°C. was on the average one-half that secured at 32°C. Pederson and Yale therefore recommended incubation of agar plates at 32°C. for 48 hours instead of at 37°C. The authors did not prove that the recommended incubator temperature had a greater relation to production conditions but based their argument entirely on the fact that higher counts were secured. In 1940 Pederson and Breed⁶⁵ claimed that it appeared to be impossible to make a perfect incubator for milk-control work. At 37°C. the plate counts would be subject to considerable uncontrolled error. They, therefore, used this as an argument for changing the incubation temperature from 37 to 32°C. because the slight variations in temperatures would be insignificant. One could ask for more evidence that the temperature variations which would occur at 32°C. are so slight that they may be ignored.

(d) *Technic of Making Counts.* Much of the discussion about plate counts is based upon results of experiments involving 100 plates from the same sample of milk. These have indicated that under the best controlled conditions, great variations in numbers of bacteria are indicated. Albus,²⁷ however, has shown that these need not be as great as have been reported. Standard methods must be closely followed. The answers which Breed⁶⁶ secured to a questionnaire on technic indicated that much is to be desired. Even though detailed directions for examining milk bacteriologically are available many laboratories were permitting marked deviations. This was shown in a striking manner by Black of the U. S. Public Health Service in a paper before the American Public Health Association in St. Louis in October, 1942.

One of the greatest opportunities for error is in counting. The personal equation is an important factor. In order to reduce the possibility of error, *Standard Methods of Milk Analysis* provides that a lens magnifying two and one-half times shall be used.

The methods used for counting colonies are very important. Robertson and Schacht⁶⁷ compared some 20 different counting equipments and found that they caused marked differences in counts on the same plates by the same counters. Further observations along these lines have been made by Schacht and Robertson²⁴ who based their statements on the results of counting contests in which some 35 individuals participated. Some individuals proved to be good counters while others were not. The former showed wide differences when their duplicate counts were compared. Schacht and Robertson found that a properly constructed plate-counting device was important. Wilson² also analyzed the magnitude of various errors involved in the plate count. For instance, in one experiment 12 plates were counted by 12 individuals who had had considerable experience. It was apparent that counting of plates by different individuals is attended by a very large error. Even when the same plate was counted by experienced workers, the values obtained fluctuated around the mean by an average figure of 30 per cent. These were believed to rest on personal bias and personal variability which vary independently from one another. These are matters which cannot be readily adjusted.

Wilson² enumerated 10 principles which should be observed in correct counting of plates.

Archambault, Curot, and McGrady⁶⁸ described a counter, as did Wilson, which has become known as the "Quebec Colony Counter." This device makes for constant and even illumination and for accuracy. This counting device is recommended in *Standard Methods for the Examination of Dairy Products*.

(e) *Sampling.* As much care as possible must be used in taking the samples. They must also be properly prepared for analysis. This is indicated by the work of Torrey and Rahe.⁶⁹ Over 90 samples of bottled milk from New York City were examined in order to study the factors which influence the distribution of bacteria in the bottle.

65. Pederson and Breed. 1940. Amer. J. Pub. Health 30, 162-164.

66. Breed. 1927. Amer. J. Pub. Health 17, 604-606; N. Y. Agr. Expt. Sta. Bull. 567.

67. Robertson and Schacht. 1931. N. Y. State Dept. Farms and Markets, Bull. 257.

68. Archambault, Curot, and McGrady. 1937. Amer. J. Pub. Health 27; 809-812.

69. Torrey and Rahe. 1910. J. Infect. Dis. 7, 377-392.

Samples were taken with the pipette, the milk dipper, and by pouring from the bottle. The conclusions reached were as follows:

The upper two ounces of the cream of fresh bottled milk of fair quality contain on the average 50 to 100 per cent more bacteria than an equal amount of the lower cream. In older and more grossly contaminated milk the lower cream may embody as many as, or even more bacteria than, the upper layers. By removing these two top ounces from a milk bottle and using the remaining top milk (eight oz.) for the infant feeding, as Hess⁷⁰ has suggested, there generally results a reduction of from 30 to 50 per cent in the bacterial count.

The dominant controlling factor in the primary distribution of bacteria in a milk bottle is the upward "rafting" activity of the fat globules. A higher percentage of bacteria are brought to the surface layers in a milk rich in cream than one poor in that substance. At ice-box temperature the rate of increase of bacteria in the cream and that in the skim milk are practically identical. As the temperature is elevated the rate of multiplication in the skim milk outstrips that of the cream until at 30°C. (86°F.) it may be many times as rapid. In certain samples of rather highly contaminated milk the abrupt change in the temperature of the environment from 5 to 30°C. (41 to 86°F.) caused a striking bacteriolysis in both the cream and the skim milk. This was probably an expression of bacterial antagonism.

The sediment portion of the average bottle of fresh milk contains frequently fewer bacteria than any other region of the fluid. A marked excess of bacteria in the sediment indicates that the milk is old or that it has been kept in a warm place.

Methods of Averaging Bacterial Plate Counts. To avoid fictitious accuracy methods have been proposed for reporting plate counts which obviate use of the actual counts obtained. It is recommended that the counts obtained by a standard technic be reported as the "plate count" and not as the number of bacteria per milliliter. It is also better to average counts in some manner. Wilson² believed the arithmetic mean for averaging plate counts to be misleading. He agreed with Robertson and Schacht⁶⁷ that the geometric mean should be used. The former was believed to be permissible for averaging the numbers of colonies on a series of plates made at the same time, but the latter should be used in most other cases. Bigger and Griffiths⁷¹ also proposed a weighted mean method of estimating the average bacterial count of a series of individual counts of milk. The weighted mean is calculated by finding the mean of a series as follows: (1) of the whole series, (2) of the whole series less the highest and lowest, and so on. This method is applicable to any series of three or more items, but the greater the number of items the more reliable are the results. The weighted mean impartially and equitably reflects the average bacterial content of milks.

A single plate count on a milk supply gives only meager information. This has been shown by series of plates poured from the same sample or dilution bottle and by plates prepared from different samples of milk. Wilson² stated that a margin of at least ± 90 per cent should be allowed on any count of raw milk based on a single plate; on two plates the allowance was ± 64 per cent and ± 52 per cent on three plates.

Practically no objection exists to averaging bacterial counts in some manner. The logarithmic average gives less weight to extremely high counts than the arithmetic average. The nature of bacterial reproduction

70. Hess. 1909. *Ztschr. Hyg.*, 62, 395-400.

71. Bigger and Griffiths. 1933. *J. Bact.* 25, 253-260.

also suggests the logarithmic average. It has been found⁷² that agar plate counts are just as variable as the microscope counts.

Another suggested method for this purpose was described by Leete.⁷³ It is known as the "three out of four" method; it was compared to the arithmetic average and logarithmic average methods for appraising the value of a series of standard plate counts when used in determining grades of milk, in degrading, and in revoking milk permits.

The method consists of taking a series of four consecutive counts; if three of the four counts are within the grade, the supply is considered officially satisfactory.

The study was made on 1,912 standard plate counts, and examples are cited showing the "three out of four" method to give a truer picture of the actual quality of the milk supply than either the arithmetic or logarithmic averages. The "three out of four" method is adaptable for milk-control administration.

The Standard Milk Ordinance and Code recommended by the United States Public Health Service, 1939,¹⁵ suggested the following method for averaging bacterial counts:

"Averaging bacterial counts in determining grades. In grading milk supplies the average of the last four consecutive counts or reductase hours is used because less than this number has been found by experience not to give a dependable picture of the bacteriological condition of a milk supply. The averaging of bacterial counts in the determination of grades under this ordinance is done by the logarithmic instead of the arithmetic method. This is because the arithmetic method is sometimes unfair to the dairyman. Suppose, for example, the laboratory reports the last four consecutive counts to be 10,000, 10,000, 10,000, and 1,000,000. The one unusually high count may have been the result of accident and is not fair cause for degrading, yet if an arithmetic average is used the milk supply will be placed in grade B, whereas its most usual quality is grade A.

For this reason the logarithmic average is specified in connection with the enforcement of this ordinance. By its use high counts are "snubbed," so to speak, unless all counts are high, in which case the snubbing effect tends to disappear and the logarithmic average approaches the arithmetic average. For example, the same counts previously listed would yield a logarithmic average of 32,000, thus keeping the milk supply in grade A, where it obviously belongs.

"How to find the average bacterial count by logarithms. The logarithms of all bacterial counts from 1,000 to 300,000,000 are given directly in the following table.* The logarithms should be entered opposite the counts in the milk control ledger. To find the average bacterial count find the average of the logarithms and then find the bacterial count in the table which is opposite the average logarithm.

Following is an example:

Counts	Logarithms
35,000	4.54
11,000	4.04
9,000	3.95
95,000	4.98
	¹ 17.51

$$^1 17.51 \div 4 = 4.38 \text{ average logarithm.}$$

72. Ann. Rept., Dept. Agr. and Markets, State of N. Y., for 1929, 109-127.

73. Leete. 1935. Twenty-fourth Ann. Rept., Internatl. Assoc. Dairy and Milk Insp., 28.

* This table is given in the original report but not in this book.

"4.38 in the table is opposite 24,000, which is therefore the average bacterial count.

"If it is found that the average logarithm occurs opposite more than one bacterial count in the table, take the lowest bacterial count as the average.

"Reductase test. When the reductase test is used the procedure shall be as follows: Follow Standard Methods of Milk Analysis except that samples are to be examined at the end of each hour but not beyond 8 hours. The reduction time shall be expressed as the number of elapsed full hours when decolorization is first observed. Samples not reduced at the end of 8 hours are to be reported as reduced in 9 hours. For purposes of grading the simple arithmetic average (not the logarithmic average) of the last four consecutive samples is to be used."

Baker⁷⁴ also suggested a method for comparing estimates of numbers of bacteria in milk.

Burri's⁷⁵ Method for Enumerating Bacteria in Milk. This procedure was developed by Burri as a substitute for the plate method. He recognized many of the inconveniences which relate to the latter. From other work, Burri noticed the regularity of drops secured by using a loop for spreading material on cover glasses. He concluded that the platinum loop ought to serve as a measure for liquids in the same manner as the pipette. Observations showed that the values found in different weighings from a loop were nearly equal, seldom varying more than five per cent and never more than 10 per cent.

The procedure involves spreading, by means of a standard loop, .001 ml. of milk being examined, on an agar slant made with two per cent agar. Such an agar gives a surface which is sufficiently firm for spreading. Each tube contains about six or eight ml. of agar medium and is so slanted that a surface about three inches in length is secured. Before use the tubes should be dried a little to give a dry surface.

A standard loop must be used which will transfer as near .001 ml. of milk as possible. It may be made of platinum wire .3 millimeter in diameter and the loop so constructed that it will be one millimeter in diameter. Hucker and Haynes⁷⁶ advised that the loop be inserted not more than two or three millimeters into the milk. It should then be touched lightly at several places on the slant followed by transverse streaking.

Dorner and Demont⁷⁷ found that in general higher counts were secured with the Burri technic than with the plate method. They stated that it was to be recommended for use in Switzerland because of its rapidity, simplicity, and inexpensiveness. A less favorable report was made by Cunningham and Andrews.⁷⁸ They found that the percentage of error in determinations made by the smear-culture technic was markedly higher than in the determinations made by plating. Evidence is presented to show that the inaccuracy of the Burri method was partially due to errors involved in loop measurements and partly to the inferiority of conditions for growth on slopes as compared with those in plate cultures.

Hucker and Haynes⁷⁶ could not recommend the Burri agar slant method for accurate counting of bacteria in milk. It was said, however, to possess practical value for controlling the sanitary quality of milk and other products. Hucker and Haynes emphasized the value of the method in determining relative rather than actual numbers of bacteria in milk and its possible use for the control of certain plant procedures in processing milk and dairy products. Since Burri proposed the method, several others have mentioned its merits. Dorner⁷⁹ used the method in a study of the

number of bacteria in freshly drawn milk. It seemed to be more satisfactory than the agar plate. Kelly⁸⁰ also used it in investigations of ropy milk outbreaks.

It is doubtful whether results of the Burri method are any more inaccurate than those secured with the agar plate. Granted however, that they are not, the Burri technic is much simpler. Burri⁸¹ again expressed his satisfaction with the test. As Weiser⁸² stated, it is a method which is of value.

Myers and Pence³¹ Procedure for Laboratory Examination of Milk. This is a simplified plating technic which employs, instead of the conventional culture dish, a culture tube which is oval in cross section; and substitutes a standard loop for the pipettes and dilution blanks normally employed. A standard .01 ml. or .001 ml. loopful of the laboratory pasteurized milk is mixed with sterile melted agar in the special culture tube and the tube is slanted so that the agar solidifies in a thin layer. The tubes are incubated and colonies counted in the usual manner. The counts obtained by this simplified procedure agree well with the standard agar plate count.

The American Public Health Association Procedure for the Plate Count of Milk.⁸³ This is the official method for bacteriological milk analysis in the United States. It is generally accepted by state and city health departments as the official procedure in their laboratories even though it is frequently not followed in detail. *Standard Methods for the Examination of Dairy Products*, in the latest edition, should be familiar to all who wish to be informed on accepted methods of milk analysis.

Medium. Previous to July 1, 1939, the standard agar medium was a simpler medium than is now official. The formulas of this medium as well as that of the new medium, official after July 1, 1939, are given in Chapter 26. The latter official medium is a tryptone glucose-meat extract-skim milk agar which, as discussed elsewhere in this chapter, gives a much higher count than the old medium. The reaction of the medium should be pH 6.6 to 7.0, preferably pH 7.0.

Dilutions. Dilution bottles should be so filled that after sterilization, they will contain 99 ml., or other amounts, of sterile water. A tolerance of two ml. of dilution water is allowed. When smaller amounts of dilution water are used, the tolerance should be proportionally smaller. After the sample has been added, the contents of each bottle should be thoroughly agitated.

The sample should be diluted so that the plates made from it will have between 30 and 300 colonies. Where it is desired to determine whether the sample exceeds some official standard such as, 10,000 or 30,000 per ml., at least two plates per sample shall be poured. If the supply is known to have a uniform bacteria content so that a single plate will show between 30 and 300 colonies, but one plate need be poured.

Counting of Colonies. All colonies on the plate should be counted after incubation for 48 hours at 37°C.(98.6°F.). A tolerance of one to three hours is permitted. When it is impossible to count the colonies at the prescribed time, they may be held in a refrigerator at less than 10°C.(50°F.) for a period not exceeding 16 hours. All colonies should be counted, including those of pin-point size.

In counting the plates, illumination and a reading lens, four to five inches in diameter magnifying about one and one-half diameters, should be used. The Quebec Colony Counter was approved.

All plate counts obtained by the standard technic shall be reported in the form "Standard Plate Count, 20,000 per ml." rather than as "20,000 bacteria per ml. as obtained by standard methods." It is also advised that counts from individual samples of milk be not publicized.

Another statement of methods of milk analysis is given in Bulletin 323 of the New York State Department of Agriculture and Markets.

Wilson's^{84, 2} Roll-Tube Method for Counting Bacteria in Milk. This method involves replacement of Petri dishes by culture tubes. Instead of delivering the inoculum into a Petri dish and pouring 10 ml. of culture media over it, the inoculum is placed in a sterile culture tube (6 x $\frac{5}{8}$ in.) containing two ml. of melted agar. After the contents have been mixed by gentle rotation, the tube is rolled rapidly under a stream of cold water so that the agar sets in a thin layer extending about one-third of the way up the tube. The tubes should be incubated mouth downward in an oblique position so that water of condensation will flow toward the plug. The preparation and use has been described by Donald.⁸⁵ Such methods would save much time and probably yield as accurate results as the plate method.

A method having much in common with the above method is the oval-tube method. These are really "flat" culture tubes which were introduced into bacteriology to facilitate study of growth on slant cultures. Myers and Pence⁸¹ adapted this tube to the enumeration of bacteria in milk. A standard loop is used for inoculating the culture tube which contains about four ml. of melted agar medium.

Procedures for Bacteriological Examination of Milk of the Ministry of Health of Great Britain.⁸⁶ These procedures are precise and indicate exactly how milk shall be examined. The other parts are given on pages 371 and 382. Three grades are recommended.

Tuberculin Tested Milk, including Tuberculin Tested Milk (Certified) : Accredited Milk.—The milk when tested in accordance with the prescribed method must not decolourise methylene blue within 4½ hours if the sample is taken at any time from the 1st May to the 31st October; or within 5½ hours if the sample is taken at any time from the 1st November to the 30th April. The milk also must not contain coliform bacillus in 1/100 millilitre.⁸⁷

Tuberculin Tested Milk (Pasteurised).—The milk must not contain more than 30,000 bacteria per millilitre.

Pasteurised Milk.—The Milk must not contain more than 100,000 bacteria per millilitre.

SAMPLING

Collection of samples.

2.⁸⁸ If the milk is in sealed bottles or cartons the sample should consist of one such bottle or carton, taken anywhere between the place of bottling and the consumer, and delivered intact to the laboratory for testing. Samples of other milk should be collected in sterile glass bottles of 2 fluid ounces capacity, provided with sterile caps or stoppers. Bottles should be filled as full as is practicable so as to permit the least possible amount of air to remain in them.

3. A convenient type of bottle in which to collect samples is one with a wide mouth having a screw thread on the outside of the neck, on to which fits a metal screw cap provided with an inner lining of rubber, or other suitable material which will withstand sterilisation by steam under pressure.

84. Wilson. 1922. *J. Bact.* 7, 405.

85. Donald. 1915. *Lancet*, Pt. 2, p. 1243; also 1916, Pt. 2, p. 423.

86. Reprinted by permission of the Controller of His Britannic Majesty's Stationery Office from Memo. 139/Foods (Jan., 1937) entitled "*Bacteriological Tests for Graded Milk*," official copies of which may be purchased from The British Information Service, 30 Rockefeller Plaza, New York, N. Y.

87. It is not necessary that every sample should be submitted to both tests, and Licensing Authorities which require to have frequent tests made of samples of producers' milk may find it convenient to have most of the samples examined by the methylene blue test alone, reserving the coliform test for occasional use.

88. These numbers appear in the regular publication. They are retained to show the sequence of the several parts of the document which are reproduced in this book.

Sampling from Churns.

4. When collecting samples from churns it is important to ensure that a sample as nearly as possible representative of the whole content of the churn is obtained. The milk in the churn should be well mixed by means of a plunger, consisting of a perforated metal disc with a long metal rod as a handle. The plunger is inserted into the churn and plunged up and down in the milk at least ten times. A sample is then removed with a sterile dipper and delivered into a sterile sample bottle. The dipper should have a pouring lip and should be provided with a hooked handle to loop over the finger of one hand whilst the lid of the churn is removed with the other. Two or three plungers should be provided so that when one is in use the others can be sterilised in a vessel of boiling water. Dippers are best sterilised by hot air at 160°C. for two hours in a hot air oven. They can be conveniently packed and sterilised in a suitable metal container and a separate dipper should be used for each sample taken.

5. The time, date and place of taking each sample should be marked on the bottle containing it.

TRANSPORT AND STORAGE OF SAMPLES**A.—TUBERCULIN TESTED AND ACCREDITED MILKS.**

6. The samples to be taken fall into two groups, viz.:—

(a) Samples of producer's milk (unbottled) taken while the milk is in the possession of the producer or before the container is opened by the dealer to whom it is consigned. In many areas the most convenient places of sampling may be the depots to which milk is delivered from a number of farms. (It is immaterial whether the special designation is used or not in relation to this milk.)

(b) Other samples (usually of bottled milk) in relation to which the special designation is used.

7. It is to be noted that the bacteriological conditions do not apply to milk in relation to which the special designation is not used (even though it is obtained from a licensed producer) when it has passed out of the possession of the producer and the containers have been opened by the dealer to whom it is consigned.

8. A sample of unbottled milk as described in paragraph 6 (a) must be kept at atmospheric (shade) temperature until 6 p.m. on the day of production if it is from a morning milking, and until 10 a.m. on the next day if it is from an afternoon milking.

9. A sample of bottled or other milk in relation to which the special designation is used (as described in paragraph 6(b)) should not be kept for the period set out in the last paragraph but it may be kept at atmospheric (shade) temperature for a period not exceeding two hours from the time of sampling. If it should not be practicable for the sample to reach the laboratory by the end of that period, it should be well packed in ice in a carrying-case.

10. In all cases if it is not convenient to begin the test at the end of the specified period (i.e. at 6 p.m. or 10 a.m. or two hours from the time of sampling as the case may be) the sample should be kept at 32° to 40° Fahrenheit. It should not in any event be so kept for more than 18 hours.

B.—PASTEURISED MILK AND TUBERCULIN TESTED MILK (PASTEURISED) (PLATE COUNT TEST).

11. On collection the bottles should ordinarily be transferred forthwith to a carrying-case and well packed in ice, and be kept in this condition until plated at the laboratory. This precaution may be dispensed with only if the bacteriologist considers it unnecessary on account of the proximity of the laboratory to the place in which the samples are collected.

C.—PLATE COUNT TEST FOR TUBERCULIN TESTED MILK (PASTEURISED) AND FOR PASTEURISED MILK

35. Samples should be examined for their bacterial content per 1 ml. in terms of numbers of bacterial colonies developing when measured quantities are mixed with nutrient agar and incubated in accordance with the following directions.

Apparatus required.

36. (1) *Dilution tubes*—as for the coliform test (paragraph 28 (b), see p. 371).
 (2) *Pipettes*—1 ml. and 9 ml. pipettes as for the coliform test (paragraphs 13 (e) and 28 (o) above).
 (3) *Petri dishes*—British Standard Specification No. 611, 1935.
 (4) *Test tubes*—as for the Methylene Blue Test (paragraph 13 (b), see p. 382).
 (5) *Water-jacketed incubator* at 37°C.

Diluent required.

37. As for the coliform test (paragraph 30, see p. 371).

Culture Medium required.

38.

Yeastrel (manufactured by Brewers' Food Supply Co., Ltd., Edinburgh.....	3 gm.
B.D.H. or equivalent Peptone.....	5 gm.
Washed shredded agar.....	15 gm.
Fresh whole milk.....	10 ml.
Distilled water	1,000 ml.

Dissolve the Yeastrel and peptone in distilled water in the steamer, and adjust the reaction at room temperature to pH 7.4, using phenol red as the indicator. Wrap the shredded agar in muslin and wash in running cold water for 15 minutes. Squeeze out the excess water and add the agar together with the freshly shaken milk to the broth. Autoclave at a pressure of 15 lbs. per square inch for 20 minutes, and filter through paper pulp in a Buchner funnel. Egg must not be used for clearing. The pulp is prepared by mashing up small pieces of "Postlip" or "White Heather" paper in water by means of a pestle and mortar. A single layer of Chardin filter paper should be laid on top of the Buchner funnel to prevent the pulp being sucked through, and the pulp itself should then be packed down evenly on top of it. The funnel should be inserted into an Erlenmeyer filtration flask fitted with a side piece. A filter pump should be applied to suck through the excess water, which should be poured off through the side piece. The filter, when ready for use, should have a total depth of about 1.5 mm. A pulp layer of suitable and approximately the same depth for any size of funnel may be obtained by pulping an area of dry "Postlip" filter paper equal to four times the square of the diameter of the funnel. With "White Heather" brand, 1 gm. of the dry paper is required for every 20 sq. cm. of funnel. Thus for a 25 cm. diameter funnel, 25 gm. of paper are required; for a 12.5 cm. funnel, 6 gm., and so on. The agar is taken directly from the autoclave and filtered hot, the whole apparatus being kept warm by a surrounding atmosphere of steam. The reaction of the filtrate is tested at 50°C. and adjusted, if necessary, to pH 7.0. The medium is tubed in 10 ml. quantities and autoclaved at a pressure of 15 lbs. per square inch for 20 minutes. The final reaction of the medium at *room temperature* should be pH 7.2.

Dilutions.

39. Dilutions of 1/10, 1/100 and 1/1000 of the milk sample, which has previously been thoroughly mixed in the way described for the Methylene Blue Test (paragraph 14 above), are to be made in the manner and with the diluent described for the Coliform Test (paragraphs 30, 31 and 32 above) except that an additional dilution, the 1/1000 dilution, is to be made from the 1/100 dilution.

Plating.

40. A fresh sterile 1 ml. delivery pipette should be introduced into the tube containing the highest dilution, with its tip not more than 1/2 to 1 inch below the level of the fluid. The fluid should be sucked up and down ten times, the contents discharged completely, a fresh 1 ml. quantity measured out, the pipette withdrawn, the tip touched against the side of the tube about 1/2 inch below the rim so as to remove any excess adhering to the outside, the contents blown out gently into the centre of a sterile Petri

dish, the tip of the pipette being held about $\frac{1}{2}$ inch above the level of the glass, 3 seconds allowed to elapse, the tip of the pipette touched against the dish at a point some distance from the fluid already delivered, and the last drop blown out. The same pipette may be used for each dilution, provided the plates are inoculated in order from the highest to the lowest dilution. It is sufficient to suck the fluid up and down 3 times in each dilution before measuring out the 1 ml. quantities for plating, except for the highest dilution which requires to be sucked up and down ten times for mixing purposes.

41. An alternative method which is somewhat quicker, is to inoculate the plates at the same time as the dilutions are made. After the 1 ml. quantity has been taken over to the next tube of diluent, the pipette may be used for inoculating the Petri dish corresponding to the dilution in which it has been washed out.

42. A sufficient number of tubes containing 10 ml. of standard milk agar are boiled up and cooled down to 45°C . The contents of one tube are delivered under sterile conditions into each Petri dish. Immediately the medium is delivered, mixing should be performed by a combination of rapid to-and-fro shaking and circular movements lasting 5 to 10 seconds, the plate being kept flat on the bench throughout the whole process. The exact procedure consists in 5 to-and-fro movements followed by 5 circular movements in a clockwise direction, succeeded by 5 to-and-fro movements at right angles to the first set followed by 5 circular movements in an anti-clockwise direction. After mixing, the plates should be allowed to stand for about an hour before being transferred to the incubator.

43. The time elapsing between the preparation of the dilutions and the pouring of the plates should not exceed 15 minutes.

44. The plates should be incubated bottom upwards for 2 days at 37°C . Water-jacketed incubators, preferably gas-heated, should be used, and the temperature in various parts of the incubator should be subject to frequent control. The plates may be piled in stacks, but unless a cellular incubator is used it is probably better not to make any stack more than 6 plates high. The incubator should be opened as little as possible during the two days.

45. A plate with more than 500 colonies should not be counted unless the plate made with the next higher dilution shows less than 30 colonies. If the plate made with the 1/1000 dilution contains more than 500 colonies it may be inferred that there are more than 500,000 colonies per 1 ml. of milk. A plate with less than 30 colonies should not be counted unless it is made with the 1/10 dilution in which case it may be inferred that there are 10 times the number of observed colonies per 1 ml. of milk. Plates should be counted within 4 hours of removal from the incubator. The best method of counting is with a specially constructed box allowing of examination of the plates by combined reflected and transmitted artificial light against a dark background with a hand magnifying glass of 4 inches focal length magnifying $2\frac{1}{2}$ diameters.⁸⁹

REPORTS

The results of the bacteriological examinations are recorded on forms provided for this purpose. They appear in the appendix of the original document.

Procedure for Determining the Total Bacterial Count of Certified Milk.⁹⁰ These prescribe a special medium but permit the new medium of *Standard Methods for the Examination of Dairy Products* if desired.

"1. Total Bacterial Counts. Total bacterial counts of Certified Milk shall be made by the agar plate method. The amounts of milk inoculated into these plates shall be 0.1 and 0.01 cc., or in such amounts as to insure plates containing more than 30 colonies and fewer than 300 colonies. The medium⁹⁰ used shall be as follows: agar, 1.5%; beef ex-

89. Suitable boxes have been described by Mattick and Hiscox, J. Scientific Instruments 10 (1933) and by Wilson.² Amer. Assoc. Med. Milk Commissions, Inc., Methods and Standards for Production of Certified Milk, New York, N. Y., 1940, p. 18.

90. Methods and Standards for Production of Certified Milk, Amer. Assoc. Med. Milk Commissions, Inc., New York, N. Y., 1940. Special media recommended may be purchased from Digestive Ferments Co., or Baltimore Biological Laboratory.

tract, 0.3% ; peptone, 1.0% ; sodium chloride, 0.5% ; dextrose, 0.1% in distilled water. The final reaction after sterilization of the medium should be pH 6.8 to 7.2. The beef extract and the peptone used shall be such as to give the highest count and the largest colonies. Wilson Nutri-Peptone or a mixture of equal parts of Difco Proteose Peptone and Tryptone have been found satisfactory. Bacto peptone has been found to be less suitable than some other brands. The colonies in the plates shall be counted after incubation for 48 hours at 37°C. In other respects the methods described in *Standard Methods of Milk Analysis* shall be followed.

“The tryptone glucose milk agar recently adopted by the American Public Health Assoc. may be used if preferred.”

The American Association of Medical Milk Commissions procedure of determining the presence of coliform bacteria in milk is given on page 373. This latter test was not approved for certified milk by Stuart *et al.*⁹¹

TABLE 3
Bacterial Count Standards Established for Milk and Milk Products
Milk Ordinance and Code Recommended by the United States Public Health Service,
Pub. Health Bull. 220.

Grade	Log average plate count per c.c. not to exceed—	Log average direct microscopic count of clumps per c.c. not to exceed—	Log average direct microscopic count of individual organisms per c.c. not to exceed—	Arithmetic average reduction time in hours to be not less than—	
				Milk, etc.	Cream ²
A consumed raw.....	50,000	50,000	200,000	8	7
B consumed raw.....	1,000,000	1,000,000	4,000,000	3½	2½
C consumed raw.....	(1)	(1)	(1)	(1)	(1)
A to be pasteurized.....	200,000	200,000	800,000	6	5
B to be pasteurized.....	1,000,000	1,000,000	4,000,000	3½	2½
C to be pasteurized.....	(1)	(1)	(1)	(1)	(1)
A pasteurized.....	30,000
B pasteurized.....	50,000
C pasteurized.....	(1)

¹ No limit. ² These arithmetic average reduction time limits represent twice the log average plate count limits corresponding to the figures in the preceding column.

Bacterial Count Standards. These are a part of practically all grading systems for milk. Each grade of milk has been given the maximum bacterial plate count which would be tolerated. If the milk could not meet this standard it was relegated to the next lower grade usually with some loss to the dealer. Such is the case, for instance, with Grade C, pasteurized milk in the United States Public Health Service Milk Ordinance and Code.¹⁵ It is milk which violates any of the requirements for Grade B, pasteurized milk. If it meets all of the requirements with exception that it has over 50,000 bacteria per ml., it is Grade C milk.

Such standards have probably been helpful for they have been a whip in the hands of a health officer, with which a producer has been driven into line. Any one who has given the matter any thought and has honestly faced the facts, will have to admit the injustice that may be done both to

91. Stuart, Wheeler, and Griffin. 1938. J. Bact. 36, 411-418.

the producer and consumer. The gross errors in counting procedures must be considered.

The best example of bacterial count standards were those published in the United States Public Health Service Milk Ordinance and Code.¹⁵ These are given in Table 3.

On several occasions, Parker⁹² has pointed out the fact that the standard plate count is not a proper criterion of quality of milk. Any one who will make an effort to secure the facts and will face them cannot help but see the merits in Parker's position. It is time that bacteriologists woke up with respect to the use of plate counts. More attention must be given to types of bacteria than to numbers. Parker⁹² stated that development of culture media to give only the maximum number of bacteria does not give a true picture of the numbers of bacteria in milk causing spoilage. He also pointed out that lowering bacterial counts has increased susceptibility to oxidized flavor in milk and surface taint in butter, owing to the upsetting of the balance in the normal bacterial flora. If the goal is zero it means reduction in quality with consequent reduction in consumption.

PRESCOTT-BREED METHOD FOR DETERMINING NUMBER OF BACTERIA IN MILK

This method is based on staining .01 ml. of milk spread in a film over one square centimeter on a clean glass slide after special treatment for removal of fat. *Standard Methods for the Examination of Dairy Products*, eighth edition, calls it the "Direct Microscopic Method." This method of counting microorganisms in a suspension by means of the microscope is of early origin. Wilson² mentioned methods proposed by Eberle,⁹³ Klein,⁹⁴ Hehewerth,⁹⁵ Eijkmann,⁹⁶ and Slack⁹⁷ as precursors. Slack's method, probably the first attempt to count bacteria in milk with the microscope, is virtually the method used today. It was used by Breed⁹⁸ and Prescott and Breed⁹⁹ for determining the number of body cells (leucocytes) in milk. Breed and Brew¹⁰⁰ and Brew¹⁰¹ later analyzed its possibilities for determining the number of bacteria in milk.

Several other investigators about this time also became interested in the technic and published methods. They were probably stimulated to do this by publication of Prescott and Breed's⁹⁹ first paper in 1910. Skar's¹⁰² method was practically identical except that the bacteria were stained in the milk. A study of the various contributions indicates that Prescott and Breed⁹⁹ were probably the originators of the present technic. Breed⁹⁸

stated that Prescott and Breed had observed during the previous year that the method could be used also for counting bacteria.

Despite most careful technic two important sources of error, according to Hanks and James,¹⁰³ hold for these methods which involve stained films: losses of bacteria from the slide during staining and faulty selection of areas for observation and counting. They recommended circular films and counting along two diameters at right angles to minimize the effect of abnormal distribution. Other factors were also discussed which suggest that microscope counts are subject to considerable error.

Relation of the Direct Microscope Count (Prescott-Breed Method) to the Standard Agar Plate Count. Introduction of this microscope method into bacteriological milk analysis made it desirable to know how results secured with it compared with those secured with the standard agar plate. Not all of those who have made such comparisons have realized just what was involved. Both methods are subject to such great errors that conclusions are almost meaningless. They are just about as valuable as would be a comparison of two measuring sticks, neither of which had any definite length and reporting the results in yards. In spite of the fact that both methods yield variable results, comparisons of results have been made.

Brew,¹⁰¹ after a rather extensive study of the question, stated that the relative differences between the two counts were greater where the bacteria are few in number. In such a case, there is probably an error in the microscope count, since it is difficult to see how it is well adapted to milk with few bacteria. Brew found a greater difference when the individual bacteria on the smear are counted than when only groups of bacteria are counted. This is said to be due to the fact that a colony on a standard plate has developed either from a single bacterium or a group of bacteria. Goodrich¹⁰⁴ reported a marked correlation between the two counts. He thought that, for accurate work, more than one slide should be prepared. This is probably one of the major objections to Prescott-Breed microscope method. Breed and Brew¹⁰⁰ compared again the relation of the two counts when studying the application of the microscope method to the control of bacteria in market milk. No general agreement was observed. Brew observed little relation between the results obtained by the plate method and the direct microscope method of counting bacteria in milk, when used for determining the number of bacteria in single samples of fresh, unpasteurized milk. There was, however, a relationship between the two counts when series of samples are examined. Brew found the microscope count to be much higher, but more accurate. The relative differences were greater between the two counts where the bacteria were few in number. In samples of milk showing plate counts of less than 10,000 per ml., the count by the microscope showed approximately 44 times as many individual bacteria; or 17 times as many when the clumps and isolated bacteria were counted as units, individual cells in the clumps not being counted. Samples

with 1,000,000 bacteria per ml. by the plate count showed about five times as many individual bacteria when the isolated bacteria and clumps of bacteria were counted as units. The number of these units was slightly less than the number of colonies given by the plate method.

Simmons¹⁰⁵ determined the bacterial content of milk by five different methods, among which were the direct microscope (Prescott-Breed) method and the standard agar plate. He believed from his work that the Prescott-Breed method was less reliable for low-count milks. Robertson⁶³ discounted Simmons' data and conclusions because he failed to take into account the effect of clumping and the possibility of making reasonably accurate counts on milks with fewer than 500,000 bacteria per ml. Breed and Stocking¹⁰⁶ also secured data with both methods. They believed that either method could be used for estimating the number of living bacteria.

Another comprehensive comparison was carried out in Breed's laboratory by Robertson. The ratio of individual microscope count to the agar plate count that occurred frequently, when the plates were incubated for five days at 37°C.(98.6°F.), was approximately four to one; when the plates were incubated for five days at 21°C.(69.8°F.), approximately two and one-half to one; when the plates were incubated five days at 21°C. with an additional two days at 37°C., approximately two to one. Since Robertson found these to be the most frequent ratios he stated that they were the most suitable ones for interpreting one count in terms of the other. As the incubation period is increased, the ratios between the two counts tended to become uniform.

Robertson found that the size of the clump indicated the quality of the milk. In good quality milk the clump was small, larger in medium quality milk, and small again in poor quality milk.

A fairly constant relation between the plate count and the Breed count of groups of bacteria in milk was reported by Kennedy.¹⁰⁷ The average relation between the plate count and Prescott-Breed group count shown by 70 comparisons was 1 to 13. No relation was found between the plate count and the Prescott-Breed count of total bacteria in milk. Milks with greater numbers of bacteria always give greater divergences between plate count and Prescott-Breed total count. Kennedy reported that the total count in milk could double without any appreciable increase in the group count, since the increase could appear in an increase of individuals in the groups. Allen¹⁰⁸ reported that the size of the groups of bacteria depended on time and temperature. Consequently, Allen thought that the relation of the plate count to the direct total count might vary with the conditions under which the milk had been kept. As was stated by Kennedy, Allen also found that the groups could undergo great increases in numbers of cells, without causing any change in the plate count.

Factors Influencing the Prescott-Breed Method for Enumerating Bacteria in Milk. As is the case with all methods of counting bacteria in milk

105. Simmons. 1919. *J. Infect. Dis.* 24, 322-336.

106. Breed and Stocking. 1921. *J. Dairy Sci.* 4, 39-72; *N. Y. Agr. Expt. Sta. Bull.* 75.

107. Kennedy. 1924. *Abs. Bact.* 8, 46.

108. Allen. 1924. *Abs. Bact.* 8, 16.

the Prescott-Breed method is influenced by many factors, a few of which are now discussed:

(a) *Bacteria in Clumps*. Individual bacteria may be counted or the clumps only. If a real attempt is being made to enumerate the bacteria in milk all cells should be counted, both the individual and those in clumps. Whether such a count would correlate well with the standard agar plate would be determined somewhat by the manner in which the sample was handled.

Whiting,¹⁰⁹ studying the number of bacteria in clumps of bacteria in market milk, found that they were somewhat dependent upon the species and the bacterial content of the milk. In low-count milk the clumps were smaller. The averages for all grades of Geneva milk were for clumps of streptococci, 26.8; *Streptococcus lactis*, 2.8; micrococci, 12.3; rods, 5.8; and yeast, 5.5.

(b) *Use With Low Count Milks*. One question about the method of estimating the number of bacteria by the direct microscope (Prescott-Breed) method has been whether it may be accurately applied to low-count milks. Different investigators have shown that with high-count milks, the Prescott-Breed method is sufficiently accurate and yields counts which are close to those secured by other methods. On low-count milks, however, there seems to be some difference of opinion. Brew and Dotterer¹¹⁰ found that the agar plate counts were higher than the microscope counts of milk with few bacteria. They explained this as due to "unrecognized contamination" on the agar plates and to overlooking bacteria in the Prescott-Breed films. These are merely assumptions and should not be considered as explanations.

The question of clumps of bacteria in milk has been reported upon at greater length by Whiting.¹⁰⁹ He found very little uniformity in the average size of clumps. Each type of bacterium showed a tendency to occur in either small clumps (*Escherichia coli*, *Streptococcus lactis*) or large clumps, (long-chain streptococci). The average size of the clump was said to be dependent on the type of organism and the conditions under which it developed. The average size of the clumps in the milks which were studied in the investigation reported, was 11.1 cells per clump. Low-count milk with less than 10,000 bacteria per ml. rarely contained clumps with more than three cells per clump. As the grade of the milk became lower and the number of bacteria increased, the size of the clump also increased. This conclusion was not in accord with earlier conclusions of Brew and Dotterer. Whiting explained the discrepancy on the basis that the milks used by the latter investigators had a large number of lactic acid bacteria. In 1929, Brew¹¹¹ published another paper on the comparative accuracy of the direct microscope and agar plate methods. However, it was stated that both methods were sufficiently accurate to control public milk supplies.

Some samples of milk are preserved for analysis. Werner¹¹² made microscope counts on a series of samples preserved with formalin. It is interesting and important from the standpoint of laboratory analyses of milk to note that microscope counts on milk two to five days old, checked very closely ("perfectly") with counts made by the same method on fresh milk. This suggested to Werner the possibility of making counts from preserved samples at a central laboratory rather than in the field. In order to determine whether this formalin would in any way effect the grading of milk by the microscope count, Werner studied the effect of formalin in a strength of 500 to 1 in milk. In only three instances would the milk have been placed in a different grade by using the count on fresh milk and preserved milk. These data would seem to make the Prescott-Breed microscope method have greater possibilities in milk-control work. The work of Hastings and Davenport¹¹³ refuted Werner's conclusions.

(c) *Use on Pasteurized Milk*. Since introduction of the Prescott-Breed method applicability with reliable results to pasteurized milk has been questioned. The question which has caused most trouble is whether the bacteria which are killed by pasteurization

109. Whiting. 1923. N. Y. Agr. Expt. Sta. Tech. Bull. 98.

110. Brew and Dotterer. 1917. N. Y. Agr. Expt. Sta. Bull. 439.

113. Hastings and Davenport. 1920. Idem 3, 494-501.

are stained, which would probably cause them to appear as living cells. Hastings and Davenport¹¹³ reported that an irregular percentage of bacteria present in milk appeared in stained and countable form after pasteurization. The number of stainable bacteria decreased in six to 24 hours after pasteurization, so that in some cases, only three per cent of the original cells could be counted. This is probably due to marked variation in staining properties of bacteria which have been subjected to heat. In 16 series of counts they varied from 18 to 83 per cent of the counts on the corresponding raw milk. Pasteurization seemed to have no effect on the stainability or countability of *Escherichia coli* and *Staphylococcus pyogenes aureus*. Cells of *Lactobacillus bulgaricum* were only faintly stained, but countable. Other bacteria gave varying results.

Ward and Myers¹¹⁴ quoted results of examinations of milk by the Prescott-Breed method before and after laboratory pasteurization and observed that the heat treatment disintegrates as well as kills the bacteria, so they are no longer countable. In their opinion the opposite view was mainly due to the multiplication of thermophiles giving a high bacterial count after pasteurization. Their essential conclusion is that insufficient numbers of dead bacteria remain after pasteurization to impair the usefulness of direct microscope counts made on pasteurized milk. Mattick,¹¹⁵ however, claimed that the Prescott-Breed microscope method did not distinguish living from dead bacteria and was, therefore, useless for pasteurized milk. He also believed that the small sample used was objectionable.

The work of Guittonneau and Brigando¹¹⁶ also showed that the staining properties of bacteria in heated milk were altered. Hempler¹¹⁷ found the microscope method of Prescott and Breed to be unsatisfactory for heated milk.

(d) *Small Samples Are Used*. This is another objection which has been made against the Prescott-Breed method. Mattick¹¹⁵ and Strynadka and Thornton¹¹⁸ both mentioned it.

Wilson² claimed that actual counts were not worth making by the Prescott-Breed method unless there is an average of at least one cell per field. Under such conditions at least 100 fields should be examined. As the average number of bacteria per field increases, the number of fields counted may be decreased.

Wilson² dealt at some length with the errors of the Prescott-Breed microscope count of bacteria in milk. The main errors were said to be due to difficulties in obtaining an adequate sample of milk, of measuring such a small sample of milk and spreading it over one square centimeter, failure of some bacteria to take the stain, and irregular distribution of bacteria over the microscope slide so that the counts of the fields vary greatly. Wilson doubted whether Breed's⁹⁸ statement that dead bacteria did not stain was true. In fact Barthel's¹¹⁹ work was quoted to show that heating had comparatively little effect on the bacteria in milk. Wilson showed that when coliform bacteria grown in milk were exposed to 63°C. (145.4°F.) for 30 minutes, they stained as deeply as before. Use of a suspension of cells grown on agar and then added to the milk, showed that many cells did not stain. Wilson stated that the Breed count was not an indication of total organisms but merely the total number of stainable bacteria, whether alive or dead.

In order to gain an idea of the variations which might be observed in this method, four individuals made Prescott-Breed films on the same sample of milk. When the bacterial content was below 500,000 bacteria per ml., the coefficients of variations were very large. For low-count milks several hundred fields should be counted to secure comparable results. These conclusions agreed with those of Buice.¹²⁰ This latter investigator considered the Prescott-Breed microscope count to be unreliable for milk with less than 200,000 bacteria per ml.

(e) *Variation in Staining Reactions of Bacteria in Milk*. Accuracy of the Prescott-Breed method rests on the supposition that all bacteria in milk stain to the same degree.

Whitehead¹²¹ reported observations which indicate that this is not always the case. In experimental work on cheese he found that the addition of Gram-negative bacilli of the colon group to milk failed to be indicated by the Prescott-Breed method. Their presence was indicated, however, by the usual culture methods. According to Whitehead, the staining ability of bacteria in milk is greatly influenced by their age. Young cells seemed to stain readily while older cells did not. Whitehead suggested that his observations might explain some of the discrepancies between the standard agar plate count and the count secured by the Prescott-Breed method.

(f) *Considerable Skill Is Required.* The Prescott-Breed method is a technical procedure requiring considerable skill and experience. Breed and Stocking¹²² stated that the chief limitations are the skill of the analyst and the patience necessary to examine a large enough amount of milk. If given enough time to examine a number of preparations, the skilled analyst can reach a fairly reliable index of the number of bacteria in milk. What constitutes a "skilled" analyst is an indefinite matter. Bacterial plate counts were said to be more regular in the hands of laboratory assistants carrying out routine analyses of milk. About the same conclusion was reached by Conn,¹²³ who stated that considerable experience was needed by the analyst to distinguish between bacteria and dirt particles.

Others who have pointed out the limitations of the Prescott-Breed method are Hastings,¹²³ and Bryan, Turney, Fox, Begeman, Miles, and Bryan.¹²⁴

Merits of the Prescott-Breed Method. While this method may not be entirely satisfactory for counting microorganisms in milk, it does have considerable value under some conditions. It is a good method for separating high-count from low-count milks. Stained films may be examined by trained workers, such as milk inspectors in the field, for rapid grading of different milks. As discussed below it gives information about the type of bacteria which are present, especially Streptococci. It is less expensive and more rapid than the agar plate method.

Detection of Abnormal Cow's Milk by Means of the Microscope. The inadequacies of microscope methods for determining the number of bacteria in milk may be somewhat compensated for by the fact that they might give valuable information concerning the presence of bacteria from diseased udders. In this way, a rapid method would be available for detecting presence of diseased cows in a herd, udders of which are shedding harmful streptococci. Practical application of such a procedure must rest on comprehensive observations on milk from cows definitely known to be shedding pathogenic streptococci and on well-trained microscopists. Forman and Shaw¹²⁵ secured samples of milk from cows showing clinical symptoms of mastitis. Samples of normal market milk and high-grade milk were also secured. The milk from infected udders contained many long-chain streptococci. Having established this, they then searched in market milk for these organisms and found them in 3.83 per cent of 261 samples examined. Results of a similar investigation were published by Breed,¹²⁶ who prepared 16 color plates. These were said to illustrate conditions in different grades of milk. They depend on the ability of the analyst to recognize streptococci solely by morphology.

Hadwen and Gwatkin¹²⁷ made counts of bacteria and body cells from whole milk and from sediments obtained by centrifuging a large number of samples drawn directly from the udders. Sediments were preferred for examination because both sufficiently accurate counts and differential studies could be made from films prepared from them.

For defining normal milk a standard was established which was used in studying milk from individual cows. In a herd of 60 cows, milk of nine met the standard. Diphtheroids were present in 70 per cent of these animals. Special attention was given to types of leucocytes. Ring-shaped polymorphonuclear leucocytes were found in staphylococcic mastitis with cocci usually present in the film. Mononuclear leucocytes were numerous in streptococcic mastitis and existed in loose irregular clumps. Organisms were frequently so scarce that special methods had to be used to prove their presence.

The microscope method was also used by Turney *et al.*¹²⁸ for determining the source of bacteria found in low-quality milk. Photographs of stained films prepared according to the Prescott-Breed method were given as an aid in identifying streptococci and determining their origin and significance. Such methods have limitations as Ferguson¹²⁹ showed. Of 292 individual udder samples obviously unfit for use, only 50 contained streptococci in numbers sufficient to be detected by the Prescott-Breed method.

Prescott-Breed Method for Direct Microscope Count of Bacteria in Milk. This method is provided for in the eighth edition of *Standard Methods for the Examination of Dairy Products*.

Samples. Retail samples should be submitted in the original container. Wholesale samples should be collected in proper sampling bottles and kept iced if not preserved with a chemical preservative. A drop of 40 per cent formaldehyde solution for each 10 ml. of milk is recommended.

Apparatus. About the only special apparatus required are special pipettes and glass slides.

Pipettes. These are specially made for this work. The most convenient form is the straight capillary pipette calibrated to deliver .01 ml., the graduation mark being one and one-half to two and one-half inches from the tip. Such pipettes are now for sale by manufacturers, and can be easily obtained. The calibration should be tested by weighing with chemical balances the amount of milk discharged from the tube. Only a single pipette is needed in making a series of tests, provided this is kept clean while in use. In this kind of work cleanliness rather than sterilization is required. Clean towels may be used for wiping the exterior of these pipettes, while their bores may be kept clean by rinsing them in clean water between each sample. The small amount of water left in the tube may be rinsed out into the milk sample under examination. This method of procedure, while adding a small number of bacteria to each sample, introduces only a theoretical error, tests showing that such bacteria cannot subsequently be detected, and make no difference in the final result.

Standard Methods for the Examination of Dairy Products does not recognize use of standardized loops for measuring the samples in official control work.

Slides and Guide Plates. Slides may be of different sizes to suit the convenience of the bacteriologist. Whatever size is adopted may be used with a guide plate on which the proper round or square areas are marked (1 sq. cm.). The squares or circles may be marked on the glass slide with a wax pencil. For routine control work, a slide two by four and one-half inches, permitting 16 such areas, is especially convenient. Slides may be provided with etched or ground margins to permit marking and labeling.

Preparation of Films. One one-hundredth milliliter of milk or cream is deposited in one of the marked areas and carefully spread over it. If the glass slide is thoroughly clean, there will be no trouble. After the film has been made, it should be dried in a warm place within five minutes to prevent growth of bacteria.

a. Dip the slide in xylene, or other suitable fat solvent for removal of fat. This will require not less than one minute. Remove and dry.

b. Immerse the slide in the staining fluid.¹³⁰ Dip the slide in the staining fluid just long enough to stain it properly. Decolorize in alcohol if overstained and dry before examination. Old or unfiltered staining fluids are to be avoided, as they may contain troublesome precipitates. The slides remain in this solution for five seconds to one minute or longer, depending upon the effect desired, and are then rinsed in water to remove the surplus stain, and decolorized in alcohol. The decolorization takes several seconds to a minute, during which time the slide must be under observation in order that the decolorization may not proceed too far before they are removed from the alcohol. When properly decolorized the general background of the film should show a faint blue tint. Poorly stained slides may be decolorized and restained as many times as necessary, without any apparent injury. After drying the slides may be examined at once, or they may be filed away and preserved for further reference.

Standardization of the Microscope. The microscope to be used must be adjusted in such a way that each field of the microscope covers a certain known fraction of the total square centimeter's area. This procedure is simple, with the proper materials at hand. The microscope should have a 1.9 mm. (1/12 in.) oil immersion objective, and an ocular giving approximately the field desired, and should preferably be fitted with a mechanical stage. To standardize the microscope, place upon the stage a stage micrometer, and by the selection of oculars or adjusting the draw tube, or both, bring the diameter of the whole microscope field to .205 mm. When so adjusted, the microscope field will cover almost exactly 1/300,000 of a milliliter of the milk (actually 1/302,840). This means that if the bacteria in one field only are counted, the number should be multiplied by 300,000 to give the total number for a milliliter. If the bacteria in a hundred fields are to be counted, the total should, of course, be multiplied by 3,000.

Inasmuch as it is difficult to count bacteria lying near the margin of the microscope field, it is much better to have an eyepiece micrometer, with a circular ruling, eight mm. in diameter, and divided into quadrants. This will give, in the microscope field, a smaller area within which the bacteria may be seen most sharply, and which may be more easily counted. Such eyepiece micrometers are now manufactured by laboratory supply houses, and may be easily obtained. In the use of this eyepiece micrometer the inner circle, by the adjustment of the draw tube, should be made to cover a circle with a diameter of .146 mm. In this case this inner circle will cover 1/600,000 of a milliliter of milk, meaning, of course, that the number of bacteria in a single field should be multiplied by 600,000, or, if a hundred fields are counted, by 6,000, to obtain the number per milliliter.

The number of microscope fields to be counted will depend somewhat upon the kind of data that are desired. If this method is to be used simply for the purpose of dividing milk into grades, it will in most cases be unnecessary to do the actual counting, since a Grade A milk will show field after field without any bacteria at all, while a Grade C milk will show the field crowded with bacteria. In all doubtful cases, however, counting

130. *Standard Methods for the Examination of Dairy Products* indicates its preparation as follows: Add .3 gm. of certified methylene blue powder to 30 ml. of 95 per cent alcohol (ethyl or denatured). Add this to 100 ml. of distilled water. Buck's phenol methylene blue staining fluid (Amer. J. Pub. Health 16 [1926], 1049) may be used, if desired, to maintain sterility.

should be done, and there should never be less than 30 fields counted in order to have reliable results. Counting 30 fields is not so tedious a task as it would seem, since, in ordinary milk, the number of bacteria in each field is small, and the counting may be done very rapidly.

Counting. Counting the bacteria in such a film may be done in two ways: (1) the number of groups of one or more bacteria present; (2) the number of individuals. The second, of course, is really the correct count of the number of bacteria, but the former will give a count much closer to that obtained by the plate count, since the colonies upon the plate represent groups of bacteria rather than individuals, each group growing into a single colony only. Extensive tests have shown that there is a fair correspondence between the number of groups reported by experienced observers and the number of colonies that may grow in plates made from the same milk, although there are occasionally discrepancies of considerable extent. These discrepancies are caused by variations in judgment as to what constitutes a group, variations in the extent to which groups break up in the dilution waters when the smears are made, and the presence of dead bacteria or of bacteria which do not grow on the plates. Some experience is needed by the microscopist in determining just what should be counted. In high-grade milks, an inexperienced person is apt to fail to recognize differences between bacteria and other minute objects. This results, as a rule, in an overcount by inexperienced men. In milk containing many readily recognizable bacteria in each field the inexperienced man is apt to overlook some of them, giving an undercount. These difficulties are overcome, however, by training and experience.

Standard Methods for the Examination of Dairy Products provides for counting as follows:

Range of individual microscope counts	Number of fields to be examined if the field diameter measures	
	.206 m.m.	.146 m.m.
Under 30,000.....	60	120
30,000 to 300,000.....	30	60
300,000 to 3,000,000.....	15	30
Over 3,000,000.....	8	15

Beattie's ¹³¹ Modification of the Direct Microscope Method (Prescott-Breed Method) for Examination of Pasteurized Milk. Beattie suggested the following procedure for using the Breed microscope method for pasteurized milk. Her procedure is based on Proca's stain for differentiating between living and dead bacteria. The following procedure was used.

Glass slides ruled with two squares of four sq. cm. each were placed on the frame of an electric stove. The stove was leveled and freshly cleaned glass slides placed over the ruled slides. A 1/100 ml. milk pipette (Bausch and Lomb) was washed in cleaning fluid (sulfuric acid and potassium dichromate), rinsed twice in fresh water, and rinsed out with the milk sample. The rinsing water was in test tubes and a separate tube of water was used at each rinsing. The sample of milk was spread over the area marked on the slide by a stiff needle set in a metal handle. The needle was flamed between samples. The films were allowed to air dry but if longer than 10 minutes was required for the process, it was assisted by gentle heat from the stove. The dried films were immersed for 20 minutes in a mixture of equal parts of ether and alcohol. The films were then air dried and immersed from one to three minutes in a mixture of eight ml. concentrated carbol-fuchsin with 100 ml. Loeffler's methylene blue. This stain differs from Proca's in that 100 ml. of distilled water are omitted from the mixture.

The dried, stained smears were examined under the microscope by artificial light with a blue glass below the condenser. A 170 mm. tube length, oil immersion lens and No. 5 ocular gave a factor of 1,200,000. For each sample of milk 300 fields were counted, the sum of the organisms in these multiplied by 4,000 gave the number of organisms per milliliter.

131. Beattie. 1927. Amer. J. Pub. Health 17, 1031-1034.

Newman's Modification of the Direct Microscope Method (Prescott-Breed Method) of Counting Bacteria in Milk. Newman¹³² believed that while the microscope method of Prescott and Breed was simple and direct, there was still a need for further simplification of the technic. Newman stated that most time and labor in the present method occurred in the treatment of the milk smear. He believed it possible to shorten this part of the technic by devising a combined procedure for extracting fat, fixation, and staining into one operation. I will quote from Newman's contribution:

"Preliminary work revealed considerable difficulty. The use of xylene, of course, precluded the use of Loeffler's methylene blue as a staining medium because the large amount of water which is contained in that dye solution is not miscible in fat solvents. However, a solution of powdered methylene blue dissolved in 95 per cent alcohol was found to combine readily with xylene. This combination gave excellent staining and fixation and the fat removal was entirely satisfactory, when freshly made. However, the preparation was not stable and after every hour or so required filtering to remove objectionable precipitates which would collect on the milk smear.

This difficulty was overcome by the addition of acetic acid. The acid not only effectively stabilized the solution but improved the fixation to a remarkable degree.

FORMULA I

Methylene blue, pwd.	2.0 gm.
Ethyl alcohol, 95%.....	60.0 ml.
Xylene, cp.	40.0 ml.
Acetic acid, glacial.....	6.0 ml.

"Dissolve methylene blue (certified) in warm (70°C. or 158°F.) alcohol, adding the powdered stain very slowly. Then add xylene and acetic acid. Filter and keep in tightly stoppered bottles.

DIRECTIONS FOR STAINING

"1. Milk smears are made on a glass slide in the usual manner. When dry, the slide is immersed in the above solution for ½ to 4 minutes. This simultaneously removes the fat from the milk, fixes the smear to the slide, and stains the bacteria and leucocytes.

(With the shorter immersion period the bacteria are well stained against a light blue background. However, when there are very few or no bacteria present on the smear, some workers prefer a four-minute immersion. This provides a more intensely blue background which facilitates focusing. There is little danger of overstaining. Slides may be allowed to remain in the solution for half an hour without injury to the smear or danger of overstaining.)

"2. Remove the slide from the solution and allow it to drain until the smear is thoroughly dry. In warm weather this seldom requires longer than half a minute.

"3. Wash thoroughly in water.

(It is very important that no water should ever be added to this or the following solutions. If by any chance water should come in contact with the smear before it has dried, the slide should be set aside until dry, then reimmersed for a moment in the solution (or in xylene), dried and then washed. If microscopic examination reveals particles of stain or of crystal-like material over the surface of the smear, the slide has been insufficiently dried and washed.)

"Comparative counts of raw and pasteurized milk, both with high and low bacterial content, revealed no apparent variation from the standard Breed method. The average counts obtained by the two methods agreed exactly.

"Recently another and more efficient fat solvent, tetrachlorethane, has been suggested as a substitute for xylene. (I wish to acknowledge the assistance of Mr. L. M. Lampert of the Dairy Laboratory, who also suggested the use of tetrachlorethane and

132. Newman. 1927. Mo. Bull. Calif. State Dept. Agr. 16, 1-7; 1926, Soc. Expt. Biol and Med. Proc. 24, 323.

pyridine which are incorporated in Formulæ II and III.) Not only does tetrachlorethane give better fat removal but there is the added advantage that it is an efficient solvent for methylene blue.

FORMULA II¹³³

Methylene blue pwd.	1 to 1.12 gm.
Ethyl alcohol, 95%.....	54 ml.
Tetrachlorethane, (tech.)	40 ml.
Acetic acid, glacial.....	6 ml.

"Add the alcohol to the tetrachlorethane in a flask and bring to a temperature not to exceed 70°C.(158°F.). If it is desired to use methyl alcohol the temperature should not be raised to more than 55-60°C. or 131-140°F., add the warm alcohol mixture to the powdered methylene blue. Shake vigorously until the dye is completely dissolved, then slowly add the glacial acetic acid to the cold stain solution. Agitate the flask during the addition of the acid. Filter the entire volume through a 15 cm. filter paper. Keep in tightly stoppered bottle.

DIRECTIONS FOR USE

1. Prepare milk smear. When dry.
2. Immerse the smear in the solution and withdraw immediately.
3. Drain until dry (30 seconds).
4. Wash in water.
5. Dry and observe.

"The advantage of this formula lies in the complete elimination of the time factor in so far as exposure of the smear in the solution is concerned. In emergencies, the smear may be washed immediately after removal from the solution, although this procedure is not recommended.

"A great advantage in the use of tetrachlorethane lies in the fact that it is an excellent solvent for methylene blue. This not only permits the use of a much smaller amount of the dye but prevents any loss of dye through precipitation as the alcohol evaporates."

Breed,¹³⁴ after giving considerable study to Newman's procedure, found Formula No. 2 to be most satisfactory. Newman told Dr. Breed he was now adding 1.12 gm. of methylene blue instead of one gram originally recommended. This allowed deeper staining. Dr. Breed commented further as follows:

"Add alcohol to the tetrachlorethane in a flask and heat to a temperature not to exceed 70°C.(158°F.) (if it is desired to use methyl alcohol, the temperature should not be raised to more than 55-60°C. or 131-140°F.). Add the combined solution to the powdered methylene blue. Shake vigorously until the dye is completely dissolved. The original directions state that the glacial acetic acid should be added at this point, but Mr. Newman writes that it is better to *cool* the solution before adding acid and that the acid should be added *very slowly*. Further heating of the acid solution should be avoided. Filter and keep in a tightly stoppered bottle.

"This solution permits much more rapid staining than does No. 1 and yields a clear, well stained preparation. The smears readily wash off the slide unless they are dried before washing (Step No. 3). If dried too rapidly the smears present a spongy appearance. If the smear is dipped in 70 per cent alcohol, this trouble may be prevented.

"At this time it might be well to mention a simplification of the method of taking samples and preparing the slides that is entirely permissible where the counts obtained are to be used in education work only, or where preliminary results are used as a means of finding milk supplies that need more careful examination later. In these cases, samples may be dipped from the weight-vat with a dipper that is thoroughly rinsed in the milk that is to be sampled. The 0.01 cc. pipette is then inserted directly into this dipper and this amount of milk withdrawn. The smear is spread immediately on a slide and placed on a suitable warm and level drying plate. Satisfactory drying plates are readily

133. Newman stated that Formula II was used for routine grading of milk in California.

134. Breed. 1929. Amer. J. Pub. Health 19, 99-100.

made by placing an electric bulb in a tin box. In the majority of milk plants, connections can be made to some electric light fixture with a suitable extension cord.

“An experienced worker can prepare slides in this way with samples from each patron almost as rapidly as the milk is dumped and weighed. Ordinarily it is possible to stain the slides in spare moments so that the slides are ready for examination by the time all of the milk has been brought to the plant (usually 9 to 10 a. m.). Thus, it is quite possible to examine an average of 200 samples of milk per day with a great saving in the preparation of sample bottles, provision for icing samples and transportation to a suitable place for making the slides. A single worker using this simplified technic has collected and examined as many as 350 samples in one day.”

Erb's ¹³⁵ Modification of the Direct Microscope Method (Breed Method) of Counting Bacteria in Milk. Erb did not find the stains suggested by Newman to be entirely satisfactory. Considerable difficulty was experienced in obtaining completely defatted milk films within a reasonable time. Consequently Erb suggested another technic. The film of milk was prepared as usual. In order to prevent growth, the films should be dried within five to 10 minutes, but excessive heat must be avoided else the films will crack and peel from the slides. When the slides are dry, they are placed in a staining solution having the following composition:

Ether (sulfuric).....	50 ml.
Methyl alcohol (absolute).....	50 ml.
Methylene blue (preferably certified).....	5 grams

Add the dye to the mixed alcohol and ether and filter through paper when dissolved. Store in a tightly stoppered bottle.

The slides should be placed in this staining solution for one minute. They should then be thoroughly but gently rinsed in water and dried in the air. They must then be examined in the usual manner.

Another microscope method was proposed by Rosan.¹³⁶ The method consists of spreading a platinum loopful (of a definite size and weight) of milk (previously heated with an equal volume of methylene blue and a little pyridin in a metal spoon) on a microscope slide, covering it with a cover glass, and counting the number of bacteria per microscopic field. The number of bacteria are calculated from this finding by means of a formula which is stated. The method is a rapid one.

Broadhurst and Paley's ¹³⁷ Single-Dip Stain for Direct Examination of Milk. This stain was developed for making direct microscope counts of milk, employing the technic ordinarily used in direct microscope examination. Like the Newman stain, it combines fat extraction, fixing, and staining.

The advantage of this stain over other methylene-blue stains is that only the organisms and other cells take the deep blue stain, while the background stains a very faint pink. This permits the counting of all organisms and shows their characteristic formation. The nuclei of the white blood cells and tissue cells take a deep blue stain, while the cytoplasm takes a faint blue. The advantages are as follows:

1. The differential background permits the counting of all organisms and shows their formations.
2. This stain permits easy differentiation between bacteria and all other cells and foreign bodies, such as precipitated dye and amorphous bodies.
3. Eyestrain in routine work is eliminated because the organisms do not have to be searched for and are not hidden by darkly stained, congealed serum solids on the smear.
4. The serum solids on a properly made smear are stained a faint pink.
5. Preparation of the stain is simple, since the reagents are easily obtainable.

135. Erb. 1929. *J. Lab. and Clin. Med.* 14, 377.
136. Rosan. 1913. *Milchw. Zentbl.* 42, 333-334.
137. Broadhurst and Paley. 1939. *J. Amer. Vet. Med. Assoc.* 47, 525-526.

6. No decolorizing of a heavily stained smear is necessary, a procedure which sometimes decolorizes organisms as well as the background, thereby causing the possibility of low counts.

Preparation of Stain. To 54 ml. of 95 per cent ethyl alcohol is added .4 ml. of concentrated sulphuric acid (c.p.). This solution is mixed with 40 ml. of technical tetrachlorethane in a flask and heated to about 55°C. (no higher). Add the combined solution while hot to from one to 1.2 gm. of methylene blue dye, shaking vigorously until the dye is as completely dissolved as possible. Next, add eight ml. of a one per cent alcoholic solution of fuchsin (prepared by dissolving one gm. basic red fuchsin in 100 ml. of 95 per cent ethyl alcohol). The stain should be mixed well, cooled, filtered, and kept in tightly stoppered bottles.

In the preparation of the stain a pipette calibrated in .1 ml. should be used for measuring the sulphuric acid, since too much acid may result in too faint a background, while too little may cause difficulty in washing the blue out of the smear.

Directions for Use. 1. Prepare the milk smear by using .01 ml. of milk spread over one sq. cm. of surface, as is the general procedure for making bacteria counts by the direct microscope method. (Two sq. cm. may be covered, if it is desired.)

2. Dry the smear on a flat surface in a warm place within five minutes.

3. When dry, dip into the stain for about 15 seconds, or flood the smear for about 15 seconds; drain off excess stain and dry while flat in a warm place.

4. Wash in cold water until all the blue is washed out of the smear and the smear assumes a faint pink color.

5. Dry, and examine under oil immersion.

Because the organisms stand out so readily in contrast to the background, much higher counts are obtained by the use of this stain than with other methylene-blue stains. It should be noted that the method is actually the same as that employed by those using the Standard Methods of Milk Analysis, except that a different stain is used. Additionally, it may be well to remark that where a smear is unevenly made, *i.e.*, where some parts are thicker than others, it may be difficult to wash out all the blue from the thickened parts of the smear. However, this does not interfere in any way with the counting of the organisms and the easy differentiation of them. In the smear of two sq. cm., all the blue is washed out perfectly.

After two years' experience with this stain, Cohen¹³⁸ suggested that much care be used in cleaning the glass slides. After drying the milk films on the slide, the Broadhurst-Paley staining solution may be applied to it with a dropper and allowed to remain for about one minute. Drain and dry carefully and immerse in a glass of cold water holding the slide vertically without shaking. Lift the slide a few times from the water and the excess stain will run off the films. Repeat this in a glass of clean water. The slide may then be dried. The technician will know when the excess stain has been removed by almost entire absence of any color left in the second glass.

Broadhurst and Long¹³⁹ suggested a new stain for milk examination. It consisted of neutral red and brilliant green and was said to give as good preparations as the methylene-blue stain of Breed and Brew.

Knaysi and Ford's¹⁴⁰ Method of Counting Viable Bacteria in Milk by Means of the Microscope. The value of such a procedure is apparent to anyone who is concerned with bacteriological milk analysis. The procedure was given by the authors as follows:

1. One ml. of the well-mixed sample is measured into each of two clean test tubes, A and B.

138. Cohen. 1940. J. Milk Tech. 3, 204.

139. Broadhurst and Long. 1932. J. Bact. 23, 57.

140. Knaysi and Ford. 1938. J. Dairy Sci. 21, 129-141.

2. To each test tube is added .5 ml. of a dye mixture containing equal parts of .2 per cent methylene blue and .2 per cent Nile blue sulfate, and the contents of each tube are mixed well. The final concentration of each dye in the completed preparation will be .025 per cent. Knaysi and Ford showed that in such concentrations these dyes were not toxic to *Streptococcus lactis* and *Aerobacter aerogenes*.

3. To one of the tubes, say tube B, add a drop of .7-.8 N NaOH and mix. Tube A receives nothing.

4. To each tube add .5 ml. of the melted and tempered hardening agent which is an agar-gelatin mixture containing two per cent agar and eight per cent gelatin, and mix the contents of each tube. Before this is done, the tubes are placed for a few moments in the water bath alongside the melted agar-gelatin mixture. The temperature of the bath should be about 45 to 50°C. (113 to 122°F.). This prevents the instantaneous hardening of the mixture. The hardening agent is now present in the concentration referred to above, namely, .5 per cent agar and two per cent gelatin.

5. With a Breed pipette, measure out .01 ml. from tube A and place on the center of the right half of a clean glass slide, and immediately cover the droplet thus formed with a clean square cover glass 1.28 x 1.28 cm. The droplet spreads and forms a film occupying the space between the cover glass and the slide.

Do the same with tube B, placing the .01 ml. droplet on the center of the left half of the slide, etc.

6. Let the preparation stand or place it in the icebox for about two minutes so that the films harden.

7. Count the blue-stained bacterial cells in a certain number of fields of each film and calculate the bacterial content of each per ml. With a 6 x 97 combination, and using 1.28 x 1.28 cm. cover glass, the factor is about 1,000,000.

The stained cells from tube A represent the dead cells present originally in the milk. The stained cells from tube B represent the total bacterial content of the milk. The difference represents the viable cells present in the milk.

With ordinary market milk it is generally unnecessary to remove the fat. If it is desired to remove the fat, the milk sample should be warmed to 35°C. to liquefy the fat; heptane is then added and shaken vigorously for three to five minutes and centrifuged. A Babcock hand or electrically driven centrifuge is sufficient. The hydrocarbon-fat layer is then removed. A convenient way of removing this layer is by suction with a capillary glass tube attached to a water pump.

This method is based on observation of Knaysi¹⁴¹ that the slightest shade of staining of the cytoplasm indicates death of the cell, while the cytoplasm of a viable cell is perfectly colorless. Knaysi and Ford found that pasteurization of milk does not render the killed bacteria invisible when their method was used. On the other hand, they confirmed earlier reports that pasteurization did render a certain percentage of the killed bacteria unstainable when the standard microscope method was used.

FROST'S MICROSCOPE METHOD FOR DETERMINING THE NUMBER OF BACTERIA IN MILK

This procedure is called the little plate method because of the fact that the microscope slide is used as a plate on which a mixture of agar medium and milk sample are incubated. Frost compared results secured with the standard agar plate with results secured with the little plate and observed good correlation. The bacterial content varied from 675 to 20,000,000 per ml. Hatfield and Park¹⁴² reported the Frost method to be just as satisfactory as the standard agar plate for good-quality milk, such

141. Knaysi. 1935. J. Bact. 30, 193-206.

142. Hatfield and Park. 1922. Amer. J. Pub. Health 12: 478-487.

as Grade A, pasteurized. They said it might be less so with milk having over 1,000,000 bacteria per ml. or where unusual types of bacteria were present. Clarenburg¹⁴³ found the method to be dependable, the best results being secured when the little plates were incubated for 20 to 24 hours at approximately 28°C. (82.4°F.). Frost, however, incubated the plates for three to 12 hours. In a comparative investigation of several different methods for determining the quality of milk Simmons¹⁰⁵ found the Frost method to yield results which agreed satisfactorily with those secured with the standard agar plate and lactose agar plate. Results with the last-mentioned medium were higher and agreed well with those secured by the Frost method. Simmons believed the Frost method to be a satisfactory method for determining the number of bacteria in milk. Comparison of the Breed, Frost, and Allen methods by Hinton¹⁴⁴ showed good correlation in most cases, although divergent results were secured on some samples. Each method was said to have its advantages. Similar conclusions were reached by Bryan *et al.*^{144a} who used the Frost method with milk, cream, and ice cream.

Wilson² gave some attention to the Frost little plate method. He stated that the procedure had some advantages over the ordinary plate method. However, he believed after considering all of the facts involved that the Frost method, as well as the Burri⁷⁵ method, gave an even less accurate estimate of the number of bacteria in milk than did the plate count. He could see no place in routine quantitative grading for either the Frost or the Burri method.

Frost's¹⁴⁵ Little Plate Method for Determining the Number of Bacteria in Milk. This method is really an adaptation of the standard agar plate so that the counts may be secured in a shorter time by means of the microscope. Professor Frost has stated the technic as follows:

APPARATUS NEEDED

Glass Slides. The apparatus needed consists, first of all, of glass slides. These must have marked off on them a definite area, of four square cm. It would seem best to have such areas permanently fixed, and slides can be purchased so marked. Since these are quite expensive, most workers will no doubt continue to use ordinary microscope glass slides (one by three inches) marked with a wax pencil. This grease border line has a distinct advantage since it causes the milk and agar to flow back and so the marked off areas are not overrun in making the "little plates." In order to have the areas accurate, it is best to use some mechanical means for the purpose of marking them. The apparatus is suggested as satisfactory, although it is possible to mark off the areas fairly accurately by tracing the lines over a paper pattern. It is economical to mark off two areas on each side.

Forceps. For handling the slides a good forceps is needed.

Warm Table. In order to prevent the hardening of the agar before it is thoroughly mixed with the milk, it is necessary to spread the little plates on a "warm table." A convenient form is a metal box surrounded with asbestos on all sides except the top and bottom. In it warm water (45°C. or 113°F.) is placed. At one end, tubulation to hold two test tubes of media are inserted at an angle of about 45 degrees.

Special Pipets. One pipet about 8 inches long made of capillary tubing is suggested. The tube should be sufficiently small so that about one-half inch will hold .01 ml. and

143. Clarenburg. 1925. Rev. in Expt. Sta. Rec. 54 (1926) 169.

144. Hinton. 1925. Abs. Bact., Abst. No. 105.

144a. Bryan *et al.* 1942. J. Dairy Sci., 25, 827-835.

145. Frost. 1921. J. Infect. Dis. 28, 176-184.

one-twentieth ml. would equal about two and one-half inches. If the pipet is marked in .01 ml., the same pipet can be used to make a direct count (Breed), as well as the little plate count. Such pipets are now stocked by most apparatus firms as "serological pipets."

Moist Chamber Cabinet. It is simply a rack to hold 48 slides and is provided with a space for water in the bottom and room on the sides for the moisture to circulate. The rack is made removable. This makes it possible to prepare all of the slides for microscopic examination without handling them individually.

Hot Plate or Drying Oven. It is necessary to dry the little plates rapidly, and this is best done by keeping them for about five minutes just below the boiling point of water. When the plates are handled individually, a metal box is used with a flat and level top in which water is kept at or near the boiling point. Where the slides are to be dried in the rack, an oven is necessary and an electric one is very satisfactory.

Staining Outfit. For the purpose of staining the individual slides a staining jar is needed. A good form is the Coplin jar. A tumbler or larger jar is needed for the wash water. In case the whole rack of slides is to be stained at once, a special container for the rack is needed.

MATERIAL NEEDED

Culture Medium. Ordinary nutrient agar is used. It is made and sterilized in the usual way (standard methods Am. P. H. Assn.).* One test tube of medium (five ml.) will be sufficient for about 50 samples.

Acetic Acid Solution. A 10 per cent solution of glacial acetic acid in 95 per cent alcohol.

Stains. Methylene blue and thionine are both satisfactory. Loeffler's methylene blue diluted with three times its volume of distilled water has been used most.

It is also possible to make a satisfactory stain by taking 10 ml. of a saturated alcohol solution of methylene blue to 400 ml. of distilled water.

The formula for the thionine stain is: thionine blue, one gm.; carbolic acid, two and one half gm., and distilled water, 400 ml.; filter. To this is added five per cent of glacial acetic acid. The slides are put in this stain without preliminary treatment with acid alcohol. We have found this the most satisfactory stain.

METHOD IN DETAIL

Melting Agar. A tube of agar is melted by placing it in boiling water. It is then placed in one of the tubulations on the warm table. The cotton plug is removed and a pipet which will deliver a small drop (about .05 ml.) is placed in it.

Filling the Warm Table. While the agar is melting, the warm table should be filled with water that has a temperature of about 45°C.(113°F.). It is necessary to note the temperature occasionally. If it gets down to 40°C.(104°F.), the agar is likely to harden, and if it gets much above 45°C.(113°F.), it is probable that some of the milk bacteria will be killed or at least devitalized to such an extent that they will not form colonies within the usual period of incubation.

Mixing the Milk. The bottle or sample should be shaken at least 25 times by tipping it from end to end slowly enough to avoid the formulation of a foam, since air bubbles would interfere with the accurate measurement of the sample in the pipet.

Sterilizing the Glass Slides. The glass slides, which have been properly marked, are sterilized in the direct flame. In order to do this, they are taken up in the forceps and passed through the flame, about three times, marked surface down, and once on the other side. About a half dozen are thus sterilized and placed on the warm table.

Pipetting the Sample. A special pipet has already been described. Approximate results can be obtained with any pipet that will measure a small quantity, as .05 ml., but since the accuracy of the count depends on the correct measurement of the sample, the construction and use of the pipet becomes a matter of great importance. It is necessary to use a pipet of small bore in order to measure accurately. This necessitates the use of heavy walled tubing. The end must be pointed, otherwise too much milk clings to the outside.

* The new plating medium now official in milk analysis could undoubtedly be used.

It is important, in using a pipet, not to dip it into the milk any farther than is necessary to avoid taking in air bubbles. The reason for this is that milk clings to the outside of the pipet and will run down and swell the sample. In any case, the tip of the pipet after it is filled should be brought in contact with the inside of the bottle above the milk to drain off the extra milk, or wiped with a piece of sterile filter paper or a sterile towel. Five one-hundredths ($1/20$) ml. of the sample of milk is placed in each area marked off on the glass slides, i.e., two equal portions from each sample are put in different squares on the same slide.

The milk portions should be put on only a few slides at once because they begin to dry before the agar is added to them, if allowed to stand on the warm table.

FIG. 3. Various apparatus used in Frost's Microscope Method of Milk Analysis.

1. Microscope glass slide with two areas of four sq. cm. each marked off with a wax pencil.
2. A guide for marking the slides.
3. Forceps provided with a stop which makes it possible to handle slides easily.
4. A "warm table." This is an asbestos covered metal box which holds about two liters of water and is used to keep the slides warm while the milk and agar are being spread to form the "little plates." It also serves to keep the tube of liquefied agar from solidifying. It has three tubulations, two at an angle for holding tubes of medium and the other for a thermometer.
5. A serologic pipet which delivers .01 ml.; .05 is the amount of milk usually used.
6. A "moist chamber cabinet." The "little plates" are kept in this while they are in the incubator. Water in the bottom keeps a moist atmosphere. The rack is made removable so that all of the slides can be dried (in an oven), fixed, and stained altogether, and thus avoiding the handling of each slide separately.
7. Field Outfit. The case is wood and is lined with an insulating material and when closed forms an incubator on the principle of a "fireless cooker." A is the "warm table" (Fig. 4) which is filled with water $42-43^{\circ}\text{C}$. B is the "moist Chamber cabinet" (Fig. 6) and contains the little plates. C is a cup which holds the agar tubes and in which they may be melted over the alcohol lamp D. E is a support for the cup and also holds the various articles in place when the case is packed. F is the cap to the alcohol lamp. G is the pipet case and H is a box in which are placed the glass slides, platinum loops, etc.
8. Carrying case packed ready to be closed. It then becomes an incubator. The outfit holds all the material necessary for making an analysis of 48 samples in duplicate.

Adding Agar and Spreading Film. As soon as possible after the milk has been put on the glass slides, a drop of agar should be added to each. An exact amount is not absolutely demanded, but it should be approximately .05 ml., and pipets should be selected that will deliver that amount in one or two drops. Practically the same amount should be used each time, otherwise the concentration of the agar will vary, and consequently, its consistency. This variation does not appear to affect the number of the colonies, but it influences their appearance.

The milk and agar must be thoroughly mixed and spread evenly over the four sq. cm. area. This is exactly done by means of a sterile platinum loop.

In order to spread the films as quickly as possible, it is desirable to have two loops and some arrangement for holding them in a flame so that one can be sterilizing while the other is in use. If the slides are properly heated at the time of sterilization, the film is easily spread and can be made to cover evenly the entire area. When the film is properly spread, it must be hardened. If the shelves in the moist chamber cabinet hold the slides in a level position, they can be put directly there, otherwise it will be necessary to arrange a place to harden them. If the work table is level, they can be placed there under a cover which will protect them from air contamination. When the film is hard, they are ready for the moist chamber and incubation.

Moist Chamber Cabinet. It is necessary to keep the little plates from drying down during incubation. For a few slides and as a makeshift Petri dishes can be used. In this case the Petri dish has the bottom covered with wet filter paper; on this are laid two glass rods or match sticks, and on these the slides may be placed, two to a dish. It is more convenient, however, to have the special apparatus designed for the purpose and called a "moist chamber cabinet," which has been described. When a considerable number of milk samples are to be examined, the cabinet is essential. It should be thoroughly cleaned from time to time to prevent contamination by such organisms as produce spreaders on ordinary plates. It is quite sufficient to wash the cabinet in hot water or boil a little water in the bottom of it by placing it over a flame. It should, of course, always be cooled before use, and when in use it should always have at least enough water in it to cover the bottom in order that the air may be kept moist.

Incubation. The little plates are best incubated at a temperature of $37.5^{\circ}\text{C}.$ ($99^{\circ}\text{F}.$). The moist chamber cabinet is put in an ordinary incubator, although a heavily insulated case, together with a source of heat, similar in principle to a fireless cooker, can be used. The possibilities of this are discussed later.

The period of incubation varies. If it is necessary to get results at the earliest possible moment, even so short a period of incubation as four hours will be satisfactory if the bacteria are actively growing in the milk at the time of sampling. If the milk has come from cold storage, has been pasteurized or is fresh and low in bacteria, seven or eight hours are necessary; if, on the other hand, there is no particular hurry about the results, the plates can be left in the incubator from one day to the next, i.e., 15 or 16 hours.

They can also be incubated at room temperature ($20^{\circ}\text{C}.$). In this case it seems necessary to leave them for at least 24 hours. Even then the count seems lower than that obtained by incubating at $37^{\circ}\text{C}.$, although this has not been fully established.

Drying Films. When the little plates are taken from the incubator, they should be dried at once. If they are allowed to dry at the room or incubator temperature, the films have a tendency to crack and to peel off or loosen in the staining process. It is best to dry the films down rapidly by putting them on a hot plate or in a drying oven at a temperature slightly below that of boiling water.

Recent trials indicate that it is possible also to put the wet films directly in the acetic acid alcohol or even the stain when it contains the acetic acid.

Staining. It is possible to stain the films so that the colonies are deeply colored, while the medium is almost wholly without color. The success of this process depends to a considerable extent on the treatment that the films receive before they are put in the stain. They must be properly dried as already indicated. They are then put in the acetic acid solution. This acts quickly but does not overact; hence, it should be applied

for about one minute, but no harm is done if the exposure is a long one. The purpose of the acetic acid is to keep the agar from taking the stain. Any of the stains mentioned are satisfactory, and the time of exposure is about two minutes, although a longer exposure is not harmful. The thionine gives excellent results. The background is clearer than with methylene blue.

The slides should be thoroughly washed in tap water. When stained, the preparation should be dried, and for this purpose a drying plate is convenient; a temperature just below 100°C. (212°F.) is best.

Dilution of Heavily Contaminated Samples. If a milk is likely to have more than one million bacteria per milliliter it should be diluted before a little plate is made. When water blanks are used, as is the common practice with the Koch plate method, comparatively little milk is taken over into the culture. If the same method were followed with the little plates, the food conditions would be quite different in the direct plates and those diluted with water. In order, therefore, to have comparable conditions in all of the little plates, it is advised that sterile milk be used for dilution purposes instead of water. It is necessary to have tubes of sterile milk containing nine ml. To these is added one ml. of the milk to be counted, and then after thoroughly mixing the diluted sample is used in exactly the same way as the ordinary samples.

A simpler way, however, is recommended, especially for field work. This was suggested by W. D. Dotterer of the Bowman Dairy Co. A small fraction of a milliliter of the milk to be analyzed is used, .01 or .02 ml. and to this, on the side, a drop of sterile milk is added from a tube which is kept in the second tubulation on the warm table. To this is added the agar, and the whole is spread with perhaps more than usual care.

Counting Colonies. The counting is done under a compound microscope. If the colonies are large and few in number, the low power can be used, and this is best. If the colonies are small or numerous, the higher powers must be used. With the immersion objective, the oil is put on the dried agar. There is no objection to mounting them in balsam and using a cover glass. This is best if the high dry powers are to be used. At first it seemed necessary to count at least 20 fields widely distributed over the film in order to get a fair average. For this a mechanical stage was recommended. Further experience leads to the conclusion that, ordinarily at least, it is only necessary to count five fields. In this case the slide is put under the microscope and moved about to get a general idea of the distribution and then five representative fields are counted. In counting, several things should be kept in mind. First, all of the colonies within the fields should be counted and only half of those that touch the edge, say those on the right half of the periphery, while those touching the left edge of the field should not be counted. Second, with the highest powers single bacteria or small groups should not be counted, on those plates that have been incubated seven or eight hours or more. In plates incubated as long as that, practically all of the original live bacteria have grown into definite colonies. Here as elsewhere, experience and good judgment are necessary to get consistent results.

Calculating the Number of Bacteria per Milliliter of Milk. Having determined the number of colonies in a given number of fields of the microscope, or the number in an average field, it is necessary to multiply that number by some factor which will convert the figures representing the number of colonies per field of the microscope into figures which will represent the total number of bacteria per milliliter of the milk.

In order to do this it is only necessary to determine the area of the microscope field, for the value of all of the other factors is known, i.e., the area of the little plates (four sq. cm.) and the amount of milk used (.05 ml., .005 ml., etc.).

$$\begin{array}{l} \left. \begin{array}{l} \text{The number of bacteria} \\ \text{per ml. of milk} \end{array} \right\} = \frac{\text{No. colonies counted}}{\text{No. fields counted}} \times \\ \\ \left. \begin{array}{l} \text{Area of little plates} \\ \hline \text{Area of the microscope field} \end{array} \right\} \quad (\text{or microscope factor}) \times \end{array}$$

Reciprocal of the dilution of the milk.

Let:

Number of bacteria per ml. of milk = X.

Number of colonies counted divided by the number of fields counted, i.e., the average number of bacteria in a microscopic field = C.

The area of the little plates (four sq. cm. or 200 sq. mm.), divided by the area of the microscope field or microscopic factor = M. The reciprocal of the dilution of the milk = D.

Then $X = C \times M \times D$. The only unknown value in the second half of the equation is the area of the microscopic field. This must be determined not only for each microscope, but also for each combination of lenses.

The area of a disk equals the radius squared times 3.14159 (π), or the diameter squared times .7854 ($\pi/4$).

In order to determine the diameter of the field of a microscope a stage micrometer is necessary. This should be ruled to .1 and .01 mm.

By regulating the length of the tube, the size of the field may be varied. It would seem desirable, however, to use the ordinary tube length, otherwise there is always danger that the tube may not be properly drawn out and the count thus affected.

For the convenience of those who may not have a stage micrometer at hand, the following table is included, which gives the approximate diameters and the areas of the microscopic fields of an American microscope. This will give a value which will serve until there is an opportunity to have the diameter of the particular microscope carefully determined.

Diameter of Microscope Fields With Common Combination of Lenses and the Tube Pushed in (160) mm.

Objective (Equivalent focus)	Ocular	Diameter of field	Area of field
2/3 inch or 16 mm.	10 x	1.55 mm.	approximately 2 sq. mm.
1/6 inch or 4 mm.	10 x	0.31 mm.	approximately 0.08 sq. mm.
1/12 inch or 2 mm.	10 x	1.555 mm.	approximately 0.02 sq. mm.

In order to make correction for eyepieces of different magnifying power, multiply the area given above for the 10 x ocular by 1.4 for an 8 x by 1.5, for a 7.5 x, by 2 for a 5 x and 2.5 for a 4 x. With a 16 mm. objective and a 10 x ocular the area of the microscope field is approximately two sq. mm. In order to get the microscope factor, the area of the little plate (400 sq. mm.) is divided by the area of the microscope field (two sq. mm.). This gives 200. This figure multiplied by the denominator of the fraction of a milliliter of the milk used in making the little plate gives the factor necessary to convert the colonies in the field of the microscope into bacteria per milliliter of milk. The usual dilution is 1/20 ml.; this means that each colony in the field of the microscope represents 4,000 bacteria per milliliter.

The same figuring would show us that each colony under a four mm. objective would mean 100,000 bacteria per ml. of milk and one colony under the oil immersion would mean 400,000 bacteria per ml. of milk.

FIELD OUTFIT

Because of the small amount of material required to make the cultures and its simplicity, this method ought to be of special value in field work.

It is shown packed and its contents are exhibited in Fig. 3. It is a case about 13¾ inches long, 13½ inches high, and 9¾ inches wide. It is lined with an insulating material. In the particular case figured, the insulating material was made of flax straw. The important dimensions are the inside ones, 10¾ inches long, 11 inches high, and 6¼ inches wide. The door is arranged to close tightly; this is accomplished by using a thick felt strip in the jamb. In this case are fitted the warm table A; the moist chamber cabinet B; a support for holding the needles and a cup for melting the agar over a

flame, E; an alcohol lamp D; a cup for holding the medium and melting it C; a pipet case G; and a box for such articles as glass slides, needles, forceps, wax pencil, etc. The case is small and packed with material necessary for duplicate plates of 48 different samples. The weight is only about 20 pounds.

If one plate only were made, 96 samples could be analyzed. If the trip were to be long, a large number of samples could be analyzed by taking extra slides, pipets, and medium, provided one set of slides was incubated and dried down before the next set of plates was made. The dried plates keep indefinitely, either stained or unstained, in slide boxes.

To use the carrying case as an incubator, it is only necessary to fill the warm table with water at about $43^{\circ}\text{C}.$ ($109.4^{\circ}\text{F}.$), pack, and close the case. When the case is kept at ordinary room temperature, the heat of the water will bring the chamber up to about that of blood heat and hold it above $30^{\circ}\text{C}.$ ($86^{\circ}\text{F}.$) for at least 12 hours. In this case the colonies grow out satisfactorily in from eight to 16 hours.

Van Oijen's¹⁴⁶ Modification of the Frost Method. The technic suggested by Van Oijen is modified from that originally published by Frost. Barkworth described it as follows: "Using a capillary pipette holding .1 ml. of milk, .05 ml. is placed in each of two grids (each 20 x 25 mm.) previously marked off on a glass slide. The slide is placed on a warm table ($47^{\circ}\text{C}.$). A similar quantity of agar medium, which has been melted and cooled to $47^{\circ}\text{C}.$, is added, mixed with the milk, and after allowing to set, the slides are incubated 16 hours at $28^{\circ}\text{C}.$ ($194^{\circ}\text{F}.$), stained, and washed and after final drying are ready for counting. The small colonies are counted under the lower power of the microscope (x 40). A special cover glass, ruled in one-mm. squares, is placed on the film, and the colonies per row or per square are counted. Good milk will have less than one colony per sq. mm."

Barkworth¹⁴⁷ found the Van Oijen modification to be more accurate than the plate-count method. He considered it to be a simple, accurate test for the bacterial content of milk. The results are secured from a considerable quantity of milk. Clarenburg¹⁴⁸ suggested that owing to overcrowding, the Van Oijen (modified) method might be best applied to milk containing over 200,000 bacteria per ml. Barkworth found that the colony counting error of Van Oijen test was about the same as that of the plate count. In the Van Oijen test a larger quantity of milk is used than in the plate test, and the author discussed in detail the extent to which this is the explanation of its increased accuracy. He concluded that probably this is not the sole factor and that it may be more accurate absolutely. Milk agar was used for the plate method to make the results more comparable, since in the slide incubation method the mixture is half milk. Better results were obtained by Clarenburg¹⁴⁸ when the little plates were incubated at $28^{\circ}\text{C}.$ ($82.4^{\circ}\text{F}.$) for 24 hours. Lorenz¹⁴⁹ concurred in this.

✓ COLIFORM BACTERIA IN MILK

Since coliform bacteria have a well-established position as indicators of pollution in water and a few other foods, much study has been given to similar application in milk. Even though many results of investigations have been published, some disagreement exists among those who have studied the question. Many of the coliform bacteria isolated from milk do not originate in milk. They belong to the aerogenes section and come

149. Lorenz. 1937. *Milchw. Forsch.* 18, 265-279.

from sources which give them no sanitary significance. Wilson² reached this conclusion after a critical appraisal of this subject. Many of the premises which validate the coliform test for water do not hold for milk. Wilson, furthermore found poor correlation between results of the coliform test and sanitary inspection of the dairy, the plate count, reduction time, and keeping quality of the milk. Some conclusions are quite to the point, for mere presence of *Escherichia coli* is not objectionable. The organism itself would be harmless. It is what it indicates that interests the sanitarian. While the source of this organism is undoubtedly bovine feces, it must be admitted that under certain conditions, it might indicate contamination with human excreta.

The Standard Milk Ordinance and Code of the United States Public Health Service for 1939,¹⁵ does not provide for use of the coliform test. *Standard Methods for the Examination of Dairy Products*, eighth edition, does include procedures for testing for the presence of coliform bacteria in milk. The American Association of Medical Milk Commissioners also provides for examination of Certified Milk for *Escherichia coli* because it considers the test to be more rigid.

Possibility of entrance of this organism is easy to explain. What happens after it has entered the milk is of great importance if it is to function as an indicator of pollution. Harrison and Vanderleek¹⁵⁰ attempted to ascertain the rate of increase of *Escherichia coli* under good, hygienic conditions, and to obtain precise information as to the restraining action of lactic-acid bacteria. At 37°C.(98.6°F.), the principal increase of organisms up to the time of curdling was due to *Lactobacillus lactis acidii*. *Escherichia coli* can increase much faster in beef broth than in milk because it is checked by the acid organisms in the latter medium. At 30°C.(86°F.) the temperature was still more favorable for *Lactobacillus lactis acidii*, which was practically the only microbe present when the milk curdled in 17½ hours. At 20°C.(68°F.), *Escherichia coli* and *Aerobacter aerogenes* increased slowly, the average time per generation for both organisms being 142 minutes. At 10°C.(50°F.) the results were irregular. The temperature was unfavorable for the *Escherichia coli* group, but there was a progressive increase of the lactic-acid bacilli. Malcolm,¹⁵¹ also, showed that various members of the coliform group grew with different rates in milk. He followed development of 75 pure cultures of members of the coliform group in sterilized milk for 24 hours at 17°C.(62.6°F.). Certain species particularly *Aerobacter aerogenes* and *Aerobacter cloacae*, multiplied much more rapidly than *Escherichia coli*. Similar results were obtained with raw milk and mixed cultures. Different results were observed, however, when higher temperatures were used. At 22°C.(71.6°F.) members of the aerogenes-cloacae section of the coliform group grew faster than *Escherichia coli*. *Escherichia coli* was said to be predominant in bovine feces, the aerogenes-cloacae types occurring in small numbers; when bovine feces were inoculated into raw milk and incubated for 36 hours at 17°C.(62.6°F.), the

151. Malcolm. 1939. J. Dairy Res. 10, 410-425.

coliform flora at the end of the incubation period were chiefly the aerogenes-cloacae types. Malcolm considered this to be important, for the latter organisms may be derived mainly from bovine feces.

These observations also explain the relatively higher incidence of the aerogenes-cloacae types in summer milk in Scotland. Such enrichment does not occur in winter, holding temperature of the milk being as a rule so low that there is little or no proliferation of any coliform types. The relative proportions of the various coliform types in winter milk tend to remain similar to those in the feces.

Presence of Coliform Bacteria in Milk. Results of many investigations which have not agreed have been reported. Ayers and Clemmer¹⁵² reviewed the problem quite well from an historical viewpoint from which it was apparent that fresh milk, even when produced under the best conditions, always contained a few *Escherichia coli*. "In fresh milk, the colon count does not indicate the extent of direct manural contamination, but does indicate the general conditions under which the milk was produced." The differentiation of *Escherichia coli* and *Aerobacter aerogenes* types was of no material value in this examination. The authors stated, however, that future studies might make it of some value. In milk of unknown history, the only meaning which might be attached to *Escherichia coli* is that high *Escherichia coli* counts indicate that it was held above 10°C. (50°F.), rarely that it was produced under very abnormal conditions. Hunter,¹⁵³ after a study of the same question, arrived at the same conclusions. Hunter found the limits of colon bacilli in fresh cow feces to be 100,000 and 10,000,000 per gram, with an average of 1,883,333. Like Ayers and his co-workers, Hunter found the colon content of milk to depend on the temperature. There seemed to be a correlation between the colon content and the total content of bacteria. Of 169 cultures isolated from fresh feces 95.2 per cent represented the fecal type. The presence and significance of the colon-aerogenes group in milk has also been investigated by Finkelstein.¹⁵⁴ With milk that was initially contaminated in the barn, 100 per milliliter were found when care was used, and 588 per milliliter when no care was used. A temperature below 10°C. (50°F.) checked the growth of the members of this group. Above 15.5°C. (60°F.) there was rapid increase. Pasteurization, properly applied, destroyed practically all of the members of this group. The effect of pasteurization on *Escherichia coli* is discussed in a subsequent chapter.

Many factors may influence contamination of milk with *Escherichia coli* as Paley¹⁵⁵ has shown. All of them should be considered when the coliform test on milk is being weighed from the sanitary standpoint. For instance, Malcolm¹⁵⁶ found that *Escherichia coli* was more prevalent in milk in summer than in winter due largely to the influence of temperature. Samples which were positive contained 613 times as many bacteria as

samples which were negative for *Escherichia coli*. A positive correlation was believed to exist between the average bacterial content of the milk, the proportion of coliform-positive samples, and the mean of the minimum and maximum atmospheric temperatures.

Methods for Detecting Coliform Bacteria in Milk. These have followed closely the methods used for the same purpose in water analysis. The same definition for the group has been followed, i.e., Gram-negative, nonspore-bearing, lactose-fermenting and growing aerobically in milk.

As Wilson² stated, two methods are available for estimating and determining the presence of coliform bacteria in milk. The first is the dilution method which consists of serial dilutions of the sample in suitable liquid medium. Lactose broth is the generally accepted medium in this country. The second method is a plating method which consists of inoculating a suitable solid medium with aliquot portions of the sample. The number of coliform colonies may then be counted.

The presumptive tests consist of the use of suitable media in which gas may be formed. These media may be either formate ricinoleate broth or brilliant green lactose bile. Gas formation in either of these media may be accepted as presumptive evidence of the presence of members of the coliform group.

The completed tests must prove that gas formation in the presumptive test was brought about by members of the coliform group and also to what section of the group they belong. Such media as Endo's agar or eosin methylene blue may be used. Poured plates of these media may be streaked from positive presumptive test fermentation tubes and incubated for 24 hours or less if possible. Typical colonies should be picked from one of these plates and studied to determine whether the characteristics mentioned above for *Escherichia coli* are fulfilled. Other tests, such as the citrate test and cellobiose fermentation, may also be applied.

Wilson found that both methods, as applied to milk, were open to serious objections. The first method had a very high sampling error and was unsuitable for the differentiation of members of the coliform group. Though the second method was ideal in theory, it was unreliable because a satisfactory medium has not yet been devised which will distinguish with certainty between coliform and non-coliform organisms or even between different types of coliform bacilli. His experience with several media indicated that fecal *Escherichia coli* grows as freely at 44°C. (111.2°F.) as at 37°C. (98.6°F.), whether in a solid or liquid medium. According to his experience no other type of coliform organism had this property. The McConkey broth medium gave more satisfactory results at 44°C. than did the modified Eijkmann medium described by Williams, Weaver, and Scherago.¹⁵⁷ Wilson stated that their experience with McConkey's medium, whether in the liquid or solid form, indicated that it never caused trouble by giving false positive reactions. He did admit, however, a slight inhibitory effect on growth of coliform organisms owing to presence of the bile salt. Comparative investigations showed that the count of coliform bacilli

157. Williams, Weaver and Scherago. 1933. Amer. J. Hyg. 17, 432.

on McConkey's medium was about 25 per cent less than that on heart extract medium without lactose or bile salt.

Wilson's experience with the citrate medium was quite successful. Evidence was also brought to suggest that in mixed cultures in raw milk at 22°C. (71.6°F.) *Escherichia coli* grew more rapidly than *Aerobacter aerogenes*; in McConkey broth the former organisms survived longer than the latter. Those who are interested in the details of laboratory technic should by all means read the discussion upon which these conclusions by Wilson were based.

Farrell¹⁵⁸ found brilliant green lactose bile broth, fuchsin lactose broth, and methylene blue-brom cresol purple broth to be the most efficient of the presumptive media for the detection of *Escherichia-Aerobacter*. The question was raised whether we possess a reliable medium for the detection of these organisms. Leahy¹⁵⁹ also reported that brilliant-green lactose bile was most suitable. Formate ricinoleate broth was also suitable for detecting coliform bacteria in milk and ice cream. Two types of media, liquid and solid, were examined by Bartram and Black.¹⁶⁰ Taurocholate agar, Wilson's hexamine agar, and Ritter's fuchsin-lactose broth gave poor confirmation of presumptive tests when compared with Endo's agar and brilliant green bile broth. Methylene blue brom cresol purple broth, formate ricinoleate broth, and desoxycholate agar yielded higher presumptive confirmation and a greater sample confirmation than Endo's agar or brilliant green bile broth. Methylene blue brom cresol purple broth gave perfect confirmation but proved somewhat inhibitive. Neutral red bile and violet red bile agar were the most satisfactory solid media and two per cent brilliant green bile the best liquid medium for isolation of *Escherichia coli* from raw, pasteurized, and certified milk. Violet red bile agar seemed to be a superior medium.

Direct plating on suitable solid media has yielded good results in the hands of some investigators. Brown and Gott,¹⁶¹ using Endo's agar for locating sources of contamination, concluded that milk does not ordinarily contain *Escherichia coli*. They believed that presence of the organism indicated undesirable conditions in production of the milk. The count on Endo's agar was also said to be a good method for following the efficiency of pasteurization. Adams and Ward attached little value to the examination of milk for *Escherichia coli*, according to the methods proposed by Brown and Gott.¹⁶¹

More recently desoxycholate agar and violet-red bile agar media have been used with satisfactory results. Use of direct plating methods would, of course, save much time. McCrady and Archambault¹⁶² stated that for the examination of dairy products containing a comparatively large number of coliform organisms the plating method would frequently be the method of choice. However, so-called "typical" colonies appearing in

162. McCrady and Archambault. 1934. Amer. J. Pub. Health 24, 122-128.

solid media pour-plates inoculated with milk may not be accepted as colonies of coliform bacteria unless a sufficiently thorough examination of a large number of colonies from representative samples has proved that they may be so accepted. The proportion of typical colonies on various solid media pour-plates which were confirmed varied from zero in some samples to 100 per cent in others.

Yale¹⁶³ also compared solid with liquid media for determining the presence of coliform bacteria in pasteurized milk. His results with culture media should be just as applicable to raw as to pasteurized milk.

Ten agar media were compared with respect to their value for plating .1- and one-ml. quantities of milk. Desoxycholate agar gave the best plates and was the only medium which showed promise where one-ml. quantities of milk were plated directly. Several bile salt agars were compared with desoxycholate agar (Baltimore Biological Laboratory) and bacto-violet red bile agar manufactured by Difco Laboratories. Both permitted the direct plating of one-ml. quantities of milk. Ingredients common to both are lactose, peptones, and neutral red indicator. From these studies based on 1,000 samples of raw milk from 85 producers colonies which are deep red in these media and are over one millimeter in diameter were found to produce gas in lactose broth in over 90 per cent of the cases. In a broad sense it was found that all red acid-forming colonies larger than .5 millimeter which grow on this media, either belong or are closely related to the coliform group. Positive results usually mean recontamination but quantitative results are not justified.

Moldavan¹⁶⁴ also recommended two per cent bile, brilliant green lactose peptone medium but the modification consists of using a plug of agar instead of estimating gas production by the use of a Durham tube. After the medium has been inoculated with one milliliter of milk and mixed, the agar in the form of two per cent is slowly poured in to make the gas seal. It is said to be quite airtight and to give quicker results than by the use of the older method.

Since Churchman's work on bacteriostasis, gentian violet has been added to the presumptive test fermentation tube media to inhibit the extraneous Gram-positive bacteria.

Kessler and Swenarton¹⁶⁵ made comparative tests of plain lactose broth, gentian violet lactose broth, and gentian violet lactose peptone bile to determine *Escherichia coli* in raw and pasteurized milk. Gentian violet lactose peptone broth was found most reliable. Gas production was found to indicate *Escherichia coli* in over 99 per cent of cases. Five per cent bile was used, but it was found that it could be reduced to one per cent with only a little loss of efficiency. No comparison was made between the value of these media and the lactose bile salt broth medium used by most English bacteriologists.

164. Moldavan. 1935. Idem 25, 1032-1033.

165. Kessler and Swenarton. 1927. J. Bact. 14, 47-53.

Demeter and his colleagues,¹⁶⁶ when studying methods for detecting *Escherichia coli* in milk, reported that violet broth and the indol test in trypsin broth gave lowest results, and gas production methods gave lower counts than did plate methods. The inhibitive action of crystal violet was marked. In one case 15.3 per cent of the cultures did not produce gas in its presence. Fermentation of carbohydrates was considered to be important with acid formation more significant than gas production. Many of the lactose-fermenters which were isolated from milk were intermediates and many were of the *Aerobacter aerogenes* type.

Smit *et al.*¹⁶⁷ secured best results with MacConkey's medium and a modified Endo's broth. The latter was said to be slightly more advantageous; it permitted both development of color and gas formation. When *Escherichia coli* is present, this medium turns red. This medium allowed information on the quality of the milk in 24 hours.

The danger of using for this purpose culture media which were developed for use in water analysis was pointed out by McAuliffe and Farrell.¹⁶⁸ Many of the media which have been used for milk carry concentrations of bacteriostatic agents found to be desirable for water analysis. Assuming the possibility of these dyes being absorbed in milk solids, studies were made by McAuliffe and Farrell to determine a more desirable dye concentration to be used in milk analysis. Whole milk was added to lactose broth containing various dye concentrations (ratio: one part of milk to 10 parts of broth). This mixture was dialyzed through a semipermeable membrane and the amount of unabsorbed dye determined colorimetrically. Results with fuchsin lactose broth show that in order to have the recommended amount of dye available (one part in 66,500) for bacteriostatic action in the presence of milk solids, the concentration of basic fuchsin should be increased seven times (to one part in 9,500). A concentration of one part basic fuchsin in 13,300 parts lactose broth was found to be noninhibitive to a skim-milk suspension of pure cultures of the *Escherichia-Aerobacter* group. Similar investigations employing brilliant green lactose bile two per cent showed that the concentration of brilliant green in this medium should be increased two and one-half times, from one part in 75,000 to one part in 30,000. It is believed that lactose broth employing these higher concentrations of dyes offers a more selective means of detecting the *Escherichia-Aerobacter* organism in milk.

Savage¹⁶⁹ believed that the *Escherichia coli* test should be used in place of the bacterial count. He had previously studied this problem and published his results in 1909-1910. Further work since then had increased his respect for the *Escherichia coli* test. He mentioned several factors which favored the organism as an indicator of undesirable conditions in milk. It is a member of a rather restricted group, the members of which multiply uniformly in milk. Furthermore, the *Escherichia coli* test gives better indication of faulty conditions of production which we have, in the

166. Demeter, Sauer, and Miller. 1933. *Milchw. Forsch.* 15, 265-280; 16 (1934), 236-276.

167. Smit, Krol, and van Wijk. 1940. *Antonie van Leeuwenhoek J. Microbiol. and Serol.* 6, 1-10.

168. McAuliffe and Farrell. 1938. *Amer. J. Pub. Health* 28, 1217-1221.

169. Savage. 1923. *Proc. World's Dairy Cong.* 2, 1295-1301.

past, tried to detect by means of the plate count. Savage's opinions are, in general, concurred in by Neri and Simonetti.¹⁷⁰

Savage stated: "For quick sorting out purposes, the following dilutions are convenient. They are added to tubes of lactose bile salt broth, and the results (positive acid and gas) are read off at once after two days' incubation at 37°C. (98.6°F.). With this medium, plating out and identification of the organism are not necessary:

Byre milk:

1 cubic centimeter of milk inoculate 2 tubes.

0.1 cubic centimeter of milk inoculate 2 tubes.

Vended milk:

0.1 cubic centimeter of milk inoculate 1 tube.

0.01 cubic centimeter of milk inoculate 2 tubes.

0.001 cubic centimeter of milk inoculate 2 tubes.

0.0001 cubic centimeter of milk inoculate 2 tubes.

Sorting standards such as the following may be used:

LACTOSE FERMENTERS OR COLI TYPE PER CUBIC CENTIMETER

Source of sample:

Byre (i.e., at cowshed):

Winter (Oct. to Apr., inclusive); Summer (May to Sept., inclusive).

Below reasonable standard if either or both 0.1 cubic centimeter tubes positive.

Vended:

Winter Unsatisfactory if both of the 0.01 and 0.1 tubes are positive, and decidedly so if lower dilutions positive.

Summer—Pass if only the 0.1 and 0.01 tubes positive; condemn if either or both 0.001 positive; between rather unsatisfactory.

Savage believed that these sorting standards applied only when no pasteurization or other form of heat had been applied. He stated also that the use of the *Escherichia coli* test on the lines recommended by him had been adopted by the Ministry of Health in connection with their graded milk requirements and standards.

Types of Coliform Bacteria in Milk. Whether the coliform test has any value in milk analysis or not, is largely dependent on the types which are found. Some members of the group may have little, if any, sanitary significance. If the test is to be of value, it must probably involve demonstration of the presence of *Escherichia coli* itself or other varieties as they may be shown to possess value as indicators of the conditions under which milk is produced and handled. Chambers¹⁷¹ reported that 65.7 per cent of coliform bacteria in milk were of the *Escherichia coli* type. Seventy-one per cent of strains isolated by Malcolm¹⁵⁶ were of this variety in the winter and spring when the cows were in the stables. During the summer and autumn this percentage dropped to 40.4 per cent. Yale¹⁷² also reported that the greater part of coliform bacteria from raw (64 per cent) and pasteurized (57 per cent) milk were of the *Escherichia coli* type. He

170. Neri and Simonetti. 1930. Ann. Ig. 40, 345-353.

171. Chambers. 1928. J. Hyg. 27, 295.

172. Yale. 1933. J. Dairy Sci. 16, 481-494.

identified many other members of the group also. Wilson² classified coliform bacteria from milk into four main groups: the *coli*, intermediate, *aerogenes-cloacae*, and irregular groups. He reported the citrate test to be one of the most reliable methods of differentiating the *coli* from the intermediate and *aerogenes-cloacae* strains. About 18 per cent of the fecal strains were found to be heat resistant. Wilson believed that the *coli* strains were derived directly or indirectly from excretal material, those of the intermediate group from soil, and the *aerogenes-cloacae* group from grains and foodstuffs.

The 310 cultures of the *Escherichia-Aerobacter* group isolated from 331 samples of raw milk by Bartram and Black¹⁷³ consisted of 57 per cent *Escherichia*, including twelve species, *Escherichia communior* predominating; 22 per cent *Aerobacter* of five species with *Aerobacter hibernicum* predominating; and 21 per cent intermediate of five species with *Citrobacter freundii* predominating. Only one of 34 pasteurized milk samples yielded *Escherichia-Aerobacter*. Of 15 cultures studied, one was *Escherichia*, one *Aerobacter*, and 13 intermediate, with *Clostridium decolorans* predominating. Eight cultures were isolated from 25 samples of certified milk, including four *Escherichia*, three *Aerobacter*, and one intermediate. This group of organisms as a whole was more significant than any one genus or species in indicating contamination. No correlation was apparent between the different media used and the genus or species isolated. Smit *et al.*¹⁶⁷ did not consider type differentiation to be important. Pure milk should be free of all types.

Significance of Coliform Bacteria in Milk. Use of these organisms as indicators of pollution in water, suggested that they might be used for the same purpose in milk analysis. The problem is to decide whether they bear any relation to the conditions under which the milk was produced. Opinion is not in agreement.

According to Zavagli¹⁷⁴ the presence of these organisms in milk is a normal condition, their numbers varying according to hygienic conditions. When precautionary measures are taken at time of production, the count should not exceed 100 per milliliter and milk to be used for market purposes should not contain more than ten per milliliter. About equal numbers of *Escherichia coli* (fecal) and *Aerobacter aerogenes* (non-fecal) types were found in market samples. The tests are of distinct value in determining the conditions under which milk has been produced. Since certain of these organisms survive pasteurization, their presence in milk does not necessarily prove that the process has not been properly conducted. The number surviving depends on the number and variety present, fat content of the milk, etc.; thus, Sherman and Wing¹⁷⁵ concluded that the test as now used in some places is of no particular value as an index to the sanitary conditions surrounding the production of raw milk. This applied to all milks except those which were so handled that bacterial growth was

prevented. For high-grade raw milks containing less than 10,000 total bacteria per milliliter the coliform test may be a supplementary index of quality, and a standard of less than 100 per milliliter for such milk would not be unreasonable. For certified milk, the standard of less than 10 coliform organisms per milliliter is not unduly stringent. If all milk were promptly cooled to 7.22°C. (45°F.) and held at that temperature, this test might prove to be of more general value.

Kon¹⁷⁶ found that a large proportion of the organisms recovered from raw milk by direct plating were of the *Aerobacter aerogenes* type with a number of "intermediates" also present. *Escherichia coli* was largely predominant in feces, while the proportion of *Aerobacter aerogenes* was very small. On the basis of this study it may be assumed that many of the coliform types of organisms found in milk originate, not from feces, but from some external source, such as contaminated utensils or feed stuffs. Davies¹⁷⁷ could see little merit in the coliform test on milk. He concluded that while *Escherichia coli* in milk, as determined by the presumptive test, indicates faulty methods in production or keeping of milk, the test does not indicate gross contamination, as it fails to distinguish organisms introduced during contamination from those subsequently grown in the milk. Furthermore, as the presumptive test fails to discriminate between fecal and non-fecal contamination it affords no indication as to the nature of the contamination. Presumptive *Escherichia coli* in milk usually results from contamination from unsterilized utensils, fecal contamination, or the growth of organisms introduced in these ways. A high *Escherichia coli* content in freshly produced milk indicates faulty production and usually the use of unsterilized utensils. A high *Escherichia coli* content at time of delivery to the consumer, when milk has been produced under reasonably clean conditions, can nearly always be attributed to keeping it at a temperature favorable to bacterial growth. Moore and Fuller¹⁷⁸ also found the colon test to be of little value for judging conditions under which milk was produced.

Yale and Ellington¹⁷⁹ believed that the colon test had only slight value as a routine test on ordinary, fresh, raw milk. High numbers of coliform organisms may not be due to manural contamination, for these organisms may grow on the utensils. The coliform test was also condemned as an accurate method for estimating dirt.

In France, Pien, Bachimont, and Filhol¹⁸⁰ considered *Escherichia coli* in milk no less significant than in water. Pasteurization at 65°C. (149°F.) for 30 minutes destroys it; hence, quantitative determinations conducted on pasteurized milk afford valuable information for control purposes. The authors devised a method which they consider more adequate to detect small numbers of this organism than those commonly used. Large quantities of

milk are first incubated at 37°C.(98.6°F.) for eight hours and one-milliliter portions are inoculated into peptone water and, after further incubation, tested for indol production. The acidity of the milk at the end of the preliminary incubation is also determined, and this value is used in estimating the number of *Escherichia coli* in the original milk.

Source of Coliform Bacteria in Milk. Whether coliform bacteria may be present in the cow's udder has not been studied much. Rowlands¹⁸¹ believed that the presence of coliform bacteria in bulk milk, where other factors show general care in production, may occasionally be associated with an udder infection with these organisms which may be detected by examination of quarter udder samples. Coliform bacteria are comparatively rare in the udder but may be the cause of mastitis. A few cases have been recorded of coliform infection without any clinical manifestations.

Van Ketel¹⁸² stated that the usual source of contamination is the feces, the body of the cow, or the feed and that the optimum temperature for growth is 37.5°C.(99.5°F.). The most obvious source of coliform bacteria would be cow feces. Kon,¹⁷⁶ however, believed that most of them came from external sources, such as utensils or feed stuffs.

Procedures for Determining Presence of Coliform Bacteria in Milk Approved by the Ministry of Health of Great Britain.⁸⁶ These are part of the entire procedure recommended for bacteriological examination of milk. References to other sections of the report refer to those sections which are quoted on pages 336 and 382.

27.⁸⁸ Samples should be examined in accordance with the following directions.

Apparatus required.

28.—(a) *Culture medium tubes*.—Test-tubes for holding culture medium conforming to the British Standard Specification 152/16, nominal 6" x 5/8", having an internal diameter of 13.5 ± 0.5 mm. should be used. Each tube should contain an inverted Durham tube conforming to the British Standard Specification 35/8, nominal 1 3/8 x 5/16", having an internal diameter of 7 ± 0.3 mm.

(b) *Dilution tubes*.—Test-tubes for dilution conforming to the British Standard Specification 152/19, nominal 6" x 3/4", having an internal diameter of 16.5 ± 0.6 mm. should be used in the two-stage method of dilution described below.

Both culture medium tubes and dilution tubes should be plugged with cotton wool or preferably covered with closely fitting aluminium caps and sterilised in the way described under the Methylene Blue Test (paragraph 13 (b) page 382).

(c) *Pipettes*.—1 ml. pipettes of the type specified under the Methylene Blue Test (paragraph 13 (e) should be used.

9 ml. pipettes with the following specification should be used:—

Overall length	360 \pm 10 mm.
Length of tapered portion forming jet.....	25 \pm 5 mm.
Distance between graduation mark and tip of jet.....	200 \pm 20 mm.
Length of tube of smaller bore at top of pipette.....	50 \pm 5 mm.
External diameter of pipette.....	10.5 \pm 0.6 mm.
External diameter of tube of smaller bore at top of pipette.....	6.0 \pm 0.5 mm.
Wall thickness of tube of smaller bore at top of pipette.....	1.0 to 1.5 mm.
External diameter of jet to be at least.....	3.0 mm.

181. Rowlands. 1939. J. Hyg. 39, 454-462.

182. Van Ketel. 1913. Rev. in Expt. Sta. Rec. 32 (1915) 577.

The pipettes should be calibrated to deliver 9 ml. of water at 20°C., when held in the vertical position and allowed to discharge by gravity in 5 to 10 seconds, the tip being touched against the side of the vessel 3 seconds after the falling column of fluid has come approximately to rest. No pipette should have an error of more than ± 1 per cent., i.e., the volume of water delivered by a 9 ml. pipette should be between 8.91 and 9.09 ml.

The pipettes containing cotton wool plugs at their upper ends should be sterilised in the way described under the Methylene Blue Test (paragraph 13 (e) page 382).

Medium.

29. MacConkey broth made according to the following formula is to be used.

MacConkey Broth (Single strength).

Commercial sodium taurocholate.....	5 gm.
Lactose.....	10 gm.
Peptone.....	20 gm.
Sodium chloride	5 gm.
Distilled water	1,000 ml.

Steam for two hours and transfer to the ice-chest overnight. Filter in the morning through Chardin paper while still cold. Adjust the reaction to pH 7.4, using phenol red as the indicator. Add about 10 ml. of 1 per cent aqueous solution of neutral red.

Culture tubes with medium added.—Distribute the MacConkey Broth Medium in 5 ml. quantities into the culture medium tubes provided with Durham fermentation tubes. Plug the culture medium tubes with cotton wool or cover with aluminium caps and sterilise in an autoclave at a pressure of 10 lbs. per square inch for 15 minutes. or in a steamer for 30 minutes on three successive days. The medium in the finished culture tubes should be clear and should have a claret-red colour free from yellow or magenta.

Diluent.

30. Tap water may be employed if it has been shown that it is free from any marked germicidal activity. Distilled water, if it has been distilled in glass *and not in metallic stills*, is also permissible. Preferably one-quarter strength Ringer's solution should be used.

Ringer's Solution (Full strength).

Sodium chloride	0.2 gm.
Potassium chloride	0.42 gm.
Calcium chloride	0.48 gm.
Sodium bicarbonate	0.2 gm.
Distilled water	1,000 ml.

The one-quarter strength solution should be sterilised by autoclaving for 20 minutes at a pressure of 15 lbs. per square inch.

Method of carrying out the Test.

31. *Filling the dilution tubes with diluent.*—9 ml. of sterile diluent are measured by means of a 9 ml. pipette and delivered by gravity in the way already described (paragraph 28 (c) above) into each of the dilution tubes after these have been sterilised.

32. *Making the dilution.*—After the milk in the sample bottle has been thoroughly mixed as described under the Methylene Blue Test (see page 383) two successive 1/10 dilutions should be made in the sterile diluent in the dilution tubes in the following way. A sterile 1 ml. pipette should be introduced into the sample bottle of milk with its tip reaching not more than $\frac{1}{2}$ to 1 inch below the surface of the milk. The milk should be sucked up and down ten times to the 1 ml. mark, and 1 ml. of milk should then be measured out, holding the pipette in the vertical position. The pipette should be withdrawn, the tip being touched against the neck of the bottle to remove

excess milk adhering to the outside; it should then be introduced into the first test-tube of the diluting series with the tip touching the side of the tube at a point about $\frac{1}{2}$ to 1 inch above the level of the diluent. It is important that the pipette should not come into contact with the diluting fluid. The milk should then be blown out, 3 seconds should be allowed to elapse for drainage, and the remaining contents blown out. The pipette should then be discarded. A fresh pipette should be introduced into the 1 in 10 dilution, with its tip reaching not more than $\frac{1}{2}$ to 1 inch below the surface of the diluent, the fluid sucked up and down ten times to the 1 ml. mark, 1 ml. measured out with the pipette in the vertical position, the pipette removed from the fluid, its tip being touched against the side of the tube about $\frac{1}{2}$ inch below the rim so as to remove any excess adhering to the outside, the pipette transferred to the second tube of the diluting series, introduced with its tip touching the side of the tube about $\frac{1}{2}$ to 1 inch above the level of the diluent, and the contents expelled in the manner described above.

33. *Inoculation and Incubation of the Culture tubes containing MacConkey Broth.*—Take a fresh 1 ml. pipette, introduce it $\frac{1}{2}$ to 1 inch below the level of fluid in the 1/100 dilution of milk, suck up and down 10 times and then transfer 1 ml. portions to each of 3 culture tubes containing MacConkey Broth using the same technique as described under making of dilutions (paragraph 32 above). Incubate the culture tubes at 37°C. for 48 hours, and then examine for acid and gas production.

Standards.

34. The milk is regarded as satisfactory in respect to this test if two out of the three tubes are found to be free from acid plus gas after 48 hours' incubation.

Procedures for Determination of Coliform Bacteria in Certified Milk.⁹⁰ "The presence of these organisms in unpasteurized milk usually indicates uncleanly milking, contaminated utensils, or improper handling of milk. Rarely they may come from infected udders. Their presence in pasteurized milk indicates improper pasteurization or contamination of the milk after pasteurization. Properly pasteurized milk should contain no organisms of the coli-aerogenes group.

"The direct plating of one ml. of Certified Milk in desoxycholate agar is recommended, since this gives a direct enumeration of coli and aerogenes colonies of characteristic red color and makes unnecessary further confirmatory tests unless it is desired to differentiate coli from aerogenes organisms. The growth of all Gram-positive organisms is inhibited.

"The use of lactose broth in fermentation tubes is not recommended since it may give either false positives or negatives and requires the use of confirmatory tests for verification. If a liquid medium is used at least 10 tubes shall be inoculated with .1 ml. of the milk to be examined."

Stuart, Wheeler, and Griffin,⁹¹ after a study of coliform bacteria from certified milk, concluded that a total coliform count was of doubtful value. Their strains were classified as *Escherichia*, intermediate, and *Aerobacter*. Their results showed wide differences in the relative proportion of these three types and no clear relation of source to type.

METHYLENE BLUE REDUCTION TEST (REDUCTASE TEST)

It has been known for a long time that milk exerts a reducing action on dyes which are put into it. Since this action was believed to be due largely to bacteria, it was logical that attempts were made to use dye reduction as a measure of bacteria in milk. Much of the earlier work has been reviewed by Wilson² whose excellent analysis of this and other pertinent problems should be examined by all milk bacteriologists. In general, reduction of methylene blue is related to bacterial activity in the

milk. Just what happens is probably not known even though many investigators have sought an answer to the question. Smidt¹⁸³ attributed reduction of the dye to an enzyme secreted in the milk to which he gave the name *aldehyde catalase*. Such explanations are opposed to the general opinion that reduction is due largely to bacterial activity or at least markedly influenced by it. Wilson has presented one of the best discussions of reducing systems in milk.

After many years' work on the reductase test, Barthel¹⁸⁴ suggested the explanation that decolorization of methylene blue in milk takes place in two phases: (1) The oxygen dissolved in the milk is consumed by the bacteria; (2) the methylene blue is decolorized by substances present in the milk itself. It has been shown since, especially by Virtanen,¹⁸⁵ that bacteria energetically reduce methylene blue. However, reduction in bacteria-free and oxygen-free milk must take place by means of substances in the milk itself; Virtanen showed that in such milk the reduction of methylene blue is brought about by citric acid acting as a hydrogen-donor, and milk salts serving as catalyzers. Milk contains about .27 per cent citric acid. Increasing the amount of sodium citrate in milk brings a corresponding shortening of the reducing time. Sodium succinate is also a hydrogen-donor, acting like citric acid.

The methylene blue reduction test may be used as a substitute for counting methods. Thornton¹⁸⁶ found it to be superior in both practice and research. This was also the experience of Nichols and Edwards¹⁸⁷ who recognized in the methylene blue reduction test a method for satisfactorily classifying milk according to bacterial quality. Not all who have studied the question concur in this opinion. Miles¹⁸⁸ considered the plate count to be superior for measuring keeping quality and commercial value of milk. The methylene blue reduction test was believed to be unsuited for examination of milk with few bacteria. According to Robertson and Frayer¹⁸⁹ this test will grade milk as good, medium, or poor but for determining the cause of poor milk one must use the microscope count. Thomas and Tudor¹⁹⁰ found the methylene blue reduction test to be a more lenient method of grading than a combination of the plate count and coliform test. A combination of the reductase test and coliform test was believed to be satisfactory.

Factors Influencing the Test. The actual conditions under which the methylene blue reduction test is carried out have a profound influence on the results secured with it. This has been revealed by various investigators. Some of these factors have not been appreciated by all who have published results of investigations. One of the first comprehensive investigations was

by Hastings, Davenport, and Wright¹⁹¹ who showed the effect of not following strictly the recommended technic.

Oxygen Content of the Milk. Davis¹⁹² mentioned this as one of the three most important factors controlling the reduction of methylene blue. The oxygen content of milk was reported by Davis to be about 25 times the equivalent of the methylene blue in the oxidized form. Most of the activity of the bacteria is therefore spent in removing this oxygen by respiration, the methylene blue not being reduced until all of the oxygen is consumed. While some investigators have believed that dissolved oxygen might be one of the disturbing factors in the methylene blue reduction test, Thornton and Hastings¹⁹³ could not agree because the rate of diffusion of oxygen into milk is quite slow and would not influence reduction time. They did agree, however, with Barthel¹⁹⁴ that disappearance of methylene blue from milk takes place in two stages: (1) removal of dissolved oxygen by bacteria, and (2) reduction of the dye by constituents of the milk. The oxygen relationship was considered to be very important but normally produced milk is usually considered to be in oxygen equilibrium with the atmosphere. Preliminary shaking did not materially affect reduction times. Milk drawn from the udder anaerobically in Jackson's¹⁹⁵ experiments reduced methylene blue almost instantly, while the same milk exposed to the air usually requires over 10 hours for a similar degree of reduction. Jackson also observed that the oxidation-reduction potential of the anaerobically drawn milk is much lower than for the same sample after exposure to air.

Influence of Light. This factor may not have received the attention which is due it in bacteriological work. In the methylene blue reduction test it is very important. Whitehead,¹⁹⁶ for instance, found that light had considerable effect on the time required for reduction. When methylene blue was added to fresh milk of good quality and the mixture exposed to sunlight at 37°C. (98.6°F.) reduction was complete "in a short time" even as low as .5 hour, whereas, "in darkness at this temperature no reduction occurred in seven hours." That reduction was not due to an enzyme was shown by the fact that "it proceeds equally well in milk which has been heated to 100°C. (212°F.) for 30 minutes. When fat was removed from the milk, no reduction was secured. This ability was restored by addition of sodium oleate. Whitehead, therefore, believed that semilight catalyzes an oxidation-reduction reaction in which unsaturated fats are oxidized and methylene blue reduced. This catalytic effect of light was also observed by Jackson¹⁹⁵ and Frayer.¹⁹⁷ Both artificial and natural light were shown by Frayer to have this ability.

Influence of Bacterial Types and Numbers. It is obvious that the reducing activities of the microorganisms which happen to be present in the milk sample will greatly influence the results of the methylene blue reduc-

tion test. In general, lactic acid-producing bacteria are active while other types are not. Fred¹⁹⁸ reported that reduction times depended on the organisms present. Hanke¹⁹⁹ stated that most bacteria have the ability to reduce the color, but the speed with which reduction is brought about depends on the nutrient media, the temperature, and the numbers of organisms present. Lactic acid bacteria are very important in the reductase test, since they are present in large amounts in milk. Hanke concluded that this test is not entirely satisfactory for determining the quality of milk, because it does not differentiate between the types of bacteria present, and various factors, such as antiseptics, may materially affect the results. Lactic acid-producing Streptococci were reported to be important in the test by Hastings, Davenport, and Wright.¹⁹¹ They were more active than coliform bacteria.

Wilson² found evidence to the effect that milk produced under aseptic conditions from a healthy udder and having a plate count of less than 100 per milliliter at 37°C.(98.6°F.), contained a natural reducing system independent of any bacteria that may be present. Pure culture studies by Jensen²⁰⁰ showed that reduction of methylene blue by lactic acid-producing Streptococci, Micrococci, and sporeformers was strongest in raw milk but more cells were needed. Alkali-forming bacteria caused slow reduction. Lactic acid-producing Streptococci caused most rapid reduction, while *Escherichia coli* and Micrococci exerted practically no influence. Another investigation along these lines by Hobbs²⁰¹ revealed presence of members of the coliform group and *Staphylococcus aureus* at time of reduction at about 37°C.(98.6°F.). In any given milk one type of organism tended to assume predominance. Hobbs isolated pure cultures and tested their reducing abilities in freshly drawn milk taken under aseptic conditions and having a plate count between 200 and 300 per milliliter. Contrary to findings of others Hobbs found a member of the coliform group to be the most rapidly reducing organism. This organism was followed by *Streptococcus lactis*, some of the fecal streptococci, *Staphylococcus aureus*, *albus* and other species. Hobbs believed this test to be a good index of the extent of bacterial metabolism in milk. Samples of milk examined by Davis and Lines²⁰³ for physiological types of bacteria involved were shown to contain, on the average, 6.27 per cent acid coagulating bacteria, 55.82 per cent acid not coagulating, 11.59 per cent acid coagulating-gas proteolytic, 16.56 per cent acid proteolytic, 2.28 per cent alkali, and 2.83 per cent inert bacteria. A wide seasonal variation was evident in physiological types of bacteria in milk. Acid not coagulating bacteria were poor reducers of methylene blue but were prominent in most high quality milk. Proteolytic types of bacteria were good oxygen absorbers and played an important part in reduction of methylene blue. There was an associative action between bacteria which usually overshadowed individual variations of reduction power.

198. Fred. 1912. Centbl. Bakt., Pt. 2, 35, 391-428.

200. Jensen. 1937. Zentbl. Bakt., Pt. 2, 96, 234-257.

201. Hobbs. 1939. J. Dairy Res. 1, 35-38.

203. Davis and Lines. 1939. J. Dairy Sci. 22, 209-218.

Marked variations in physiological types of bacteria present in individual samples failed to have any material effect on reduction times.¹ Acid coagulating, alkali forming, and inert bacteria appeared to have an effect on reduction rates unless present in unusually large numbers. Guglielmo²⁰⁴ also found milk free from *Escherichia coli* to give a longer reduction time than milk in which this organism was abundant.

Influence of Temperature of Incubation. Evidence is available to show that temperature is an important factor in reduction of methylene blue in milk. That is the reason for regulating to 37°C. and preferably using water baths instead of incubators. Wilson² compared the reduction times of identical milks at 35, 37, and 39°C. (95, 98.6, and 102.2°F.). Considerable difference in results was noticed. With Grade A raw and pasteurized milk reduction was most rapid at 39°C.; with other types of raw milk, it was most rapid at 35°C. The larger the content of saprophytic microorganisms, the more likely is the reduction time to be shorter at 35°C. than at 39°C.; larger proportions of parasitic and heat-resistant organisms reverse this situation. The higher temperatures accelerate the chemical reactions involved in reduction and reduce the amount of dissolved oxygen.

Braz and Hoy²⁰⁵ also found that temperature was important and if not controlled would introduce large errors. In practice wide variations in temperature may occur. A series of tests showed that storage for 12 hours at 18.3°C. (65°F.) is equivalent to 18 hours at 15.5°C. (60°F.). A temperature of 4.4 to 10°C. (40 to 50°F.) has a considerable retarding effect on the test, but a storage temperature of 60°F. reveals a milk in its true character. This temperature was considered too high by Powell, Jenkins, and Thomas.²⁰⁶ Holding at 4.4°C. (40°F.) in the winter retarded reduction while 15.5°C. (60°F.) was too drastic in summer. Johns²⁰⁷ suggested a procedure which involved preliminary incubation at 12.8°C. (55°F.) for 18 hours followed by mixing of the contents of tubes not decolorized in six hours when subsequently incubated at 37°C. (98.6°F.). Both modifications shortened reduction time; the mixing reduced variations between duplicate tubes.

Chalmers²⁰⁸ believed that examination of milk within four hours of the time of its production gave misleading indication of its keeping quality.

Testing milk by the methylene blue reduction test too soon after production does not permit distinction of good milk from bad milk. Time must elapse to permit sufficient growth of bacteria to make the reduction test of value. The "Guide to the Conduct of Clean Milk Competitions" of the Ministry of Agriculture and Fisheries of Great Britain has stipulated examination not sooner than 20 hours and not later than 30 hours after production.

Effect of Shaking the Tubes During Reduction. The main difference between the old and modified technics, is that of agitation. Wilson² stud-

204. Guglielmo. 1940. Gior. di Batteriol. e. Immunol. 24, 233-252.

208. Chalmers. 1938. J. Dairy Res. 9, 351-353.

ied this question carefully before suggesting his new modified technic. He believed that the effect of inversion of the tubes is twofold, to mix the fat with the milk and thus maintain a more even distribution of bacteria, and to aerate the milk and increase its dissolved oxygen content. Wilson found that the first shortened reduction time; the second explanation (aeration) accelerated reduction in so far as it led to more rapid growth of bacteria in the milk. Consequently Wilson carried out comparative studies which prompted him to recommend inversion of the tubes during the reduction period. The observations of Johns²⁰⁹ and Frayer²¹⁰ confirmed this opinion. On the other hand, Thornton²¹¹ observed so little effect of inversion of the tubes that he did not recommend it. He found no reason for adopting the modified test on this continent. Johns pointed out that the methylene blue reduction test is based on the rate of oxygen consumption in the milk by bacteria during incubation. This rate cannot be measured with reasonable accuracy where varying proportions of the bacteria are removed from the main body of the milk during creaming process. Williams, Davies, and Thomas²¹² shook stoppered tubes and correlated reduction time with off flavors. Immersion at half-hour intervals decreased reduction time of poor-quality milks by a few minutes only but of good milk by about 10 hours.

Amount of Methylene Blue. This has been found to have marked influence on the test. Fay²¹³ observed that, when varying amounts of dye solution were added the reduction time was directly related to the amount added. This relationship indicated the gross errors which would be introduced by careless measurement of the dye solution. This subject was discussed much earlier by Hastings, Davenport, and Wright.¹⁹¹ They believed that one part of crystalline dye in 200,000 parts of milk gave a satisfactory color.

Relation of Reduction Time to Number of Bacteria in Milk. Since bacterial counts are one of the older methods for examining milk, they have been compared with reduction time to determine whether the simpler methylene blue reductase test could not replace the count. Barthel²¹⁴ concluded that it furnished a quicker means for judging milk than the fermentation test. He added .5 ml. of methylene blue solution in 10 ml. of milk, the mixture being covered with a few drops of liquid paraffin and placed in an incubator at 40 to 45°C. (104 to 113°F.). If the color disappeared in a few minutes, the milk contained 100,000,000 bacteria per ml., or more. If the dye was not reduced in three hours, the milk was said to be good market milk. Tromsdorff²¹⁵ stated that fresh, bacteria-free milk contained no reductase. Hoyberg,²¹⁶ believing that methylene blue might be reduced by various substances, stated that the test might have no relation to the

bacteria present. Rahn²¹⁷ believed that the test was useful only for mixed milks, and that it was subject to variation owing to temperature and other factors. Smith,²¹⁸ while believing that there was satisfactory correlation between the count and the results of the methylene blue reduction test, believed that it was not accurate for grading.

Hastings²¹⁹ stated that the reduction test determined the number of bacteria as accurately as could be done by any method. After considerable study, Hastings suggested the relation of the reduction time to the count. He examined the milk by the Breed method, the Frost little plate, and the standard agar plate. Tennent²²⁰ also studied the relation between the agar count and the reductase test. Campbell²²¹ observed a relation between the results of the reductase test and the bacterial count.

Hastings, Davenport, and Wright¹⁹¹ reported a continuation of Hastings' work on this test. They found no differences of any practical importance between the reduction times of dyes of domestic and foreign manufacture. Any impurities which might have been present were said to be diluted so much that they were of no significance. The temperature of 38°C.(100.4°F.) seemed to be as good as any other for a series of samples was found to be placed in the same order, no matter what temperature was used. The reduction test was stated to be only a rough indication of the general condition of the milk. The great heterogeneity of the flora of milk seemed to indicate that any one test should not be used for determining milk quality. This opinion was also expressed by Barthel.¹⁹⁴ Dahle and Martin²²³ also observed a satisfactory correlation between the bacterial content and the methylene blue reduction test. This was not true, however, with low-count milks. Ellenberger, Bond, Robertson, and Moody²²⁴ found the results of the reduction test more consistent than mere plate counts. Lerner and van Gelder,²²⁵ Hiscox,²²⁶ and Straub²²⁷ were in agreement. Beutler,²²⁸ however, did not agree with this conclusion. More recently a few others have found the reduction time to agree well with the plate count.

Fairer²²⁹ concluded that both the bacterial count and reductase test yielded similar results; the former, being quantitative, may be of greater assistance to the producer. Sandberg²³⁰ confirmed this. Faulds²³¹ found the methylene blue reduction test yielded 75 per cent of comparable results. It was more stringent in warm weather and less so in cold weather.

A comparison of the plate count and methylene blue reduction test by Barkworth and Mattick²³² showed that 87 per cent of samples failed to pass both tests. The correlation between plate count and reduction time was lower in winter, although here a high correlation was found with high-plate count. Four laboratories testing common samples agreed on plate counts and reduction times at 37°C., but gave differences with the keeping quality test and the reduction test at 15.5°C.

Few investigators on this continent have studied the methylene blue reduction test as thoroughly as Thornton and his colleagues. He has used it in the field to determine reasons for non-compliance with milk regulations. In one experiment (Thornton²³³) he found that dirty utensils were the cause of the trouble. Marked extension of the reduction time was observed when utensils were sterilized. Discrepancies between reduction time and plate counts were observed; the former was believed to be a better measure of the conditions than the plate count. It is interesting to note that the standard of over five and one-half hours' reduction time was attained by no other effort than sterilizing utensils. This was also shown in investigations by Stott and Barkworth²³⁴ and Nichols and Edwards.¹⁸⁷

Some attention has been given to the possibility of using the methylene blue reduction test for detecting the presence of abnormal milk. Devereux and Bryan²³⁵ found that it did. When only 10 per cent of mastitis milk was present reduction time was significantly reduced. They attributed this sharper reduction to presence of large numbers of leucocytes. Strynadka and Thornton²³⁶ emphasized the need for careful reasoning on the relationship of leucocytes and reduction time. They believed that the abnormal udder conditions responsible for milk of high leucocyte content are also responsible for abnormally high concentrations of reducing substances in milk. Presence of such high concentrations of reducing substances would explain the rapid reduction of methylene blue without the aid of leucocytes. This is not a denial of the possibility that some leucocytes possess reducing properties, but the bulk of evidence indicates that leucocytes are rarely, if ever, the main or significant influence in the reduction of methylene blue.

Methylene Blue Tablets. Some difficulty is frequently experienced in the use of domestic varieties of methylene blue. Wall and Robertson²³⁷ reported that the addition of a small amount of calcium carbonate, sodium carbonate, or sodium bicarbonate to the aqueous solutions of these samples made them more satisfactory. This was said to prevent dissolution of the film by the staining fluid. Barthel and Jensen²³⁸ suggested that tablets of methylene blue, as put up by Blauenfeld and Tvede, be used as the standard product for reductase tests. The National Aniline and Chemical Co. has prepared similar tablets for the American trade. Grimes, Boyl, Barrett, and Reilly²³⁹

did not experience much trouble with various brands of dye. Stock solutions used in preparing dilute solutions were found to be stable for nine months. The longer the reductase time, the greater the variation between duplicate and triplicate tests. A large variation in the ratio of methylene blue to milk does not alter the grade of the milk, particularly if the milk is reduced in less than two hours. Fay²⁴⁰ stated that the amount of dye solution used should be measured very carefully, as an error of .5 ml. caused a variation in time of reduction of from 30 to 47 minutes. Ellenberger and Moody²⁴¹ reported that certain refinements in technic were not as necessary as in other methods of milk examination. Methylene blue tablets were found to be heavily contaminated with rods by Mattick and Neave.²⁴² No effect was observed on the reduction test at 37°C.(98.6°F.). It would probably be good practice to examine the methylene blue solutions occasionally by plating and to store them in a cool place.

Variability among different lots of dyes has caused the necessity of attempting to standardize them in some manner. Thornton and Sandin,²⁴³ after studying the purity of methylene blue dyes, recommended the use of methylene blue thiocyanate for use in the reductase test. They further recommend a concentration of one part of dye in 300,000 parts of milk. Tablets have been available in the past for convenience to make preparation of the methylene blue solution easier. Thornton and Sandin, however, found them wanting. They recommended new tablets of methylene blue thiocyanate. The Committee of the Laboratory Section of the American Public Health Association on Examination of Dairy and Food Products approved this recommendation.²⁴⁴ *Standard Methods for the Examination of Dairy Products* permits use of such tablets which have been approved by the Biological Stain Commission. One tablet is dissolved in 200 milliliters of freshly boiled distilled water. Conn²⁴⁵ believed that American manufacturers could put out a very uniform product. He showed that the concentration of dye actually obtained with the chloride was near 1-700,000. Changing the strength of the dye solution has altered the reduction times. Johns²⁴⁶ reported that the average increase in reduction time using the new methylene blue solution (thiocyanate 1-300,000) for summer milks is around 30 minutes. This was said to be due to the lower potential at which the dye-milk mixture reduces.

PROCEDURES FOR THE METHYLENE BLUE REDUCTION TEST

In view of the fact that the methylene blue reduction test is influenced by so many different factors, several different procedures have been proposed, in each of which some special factor, which was supposed to improve the test, has been emphasized. Probably the most profound change in technic has been inversion of the tubes containing the mixture of milk and dye solution at half-hour intervals, as proposed by Wilson.²

American Public Health Association Procedure for the Reductase Test. Measure 10 ml. of milk with a sterile pipette or dipper into the test tubes in which the test will be made. Use sterilized apparatus. Add one ml. of methylene blue thiocyanate solution from a burette or with a one-ml. pipette. Stopper the tubes immediately and place them in the water bath at 37°C. (98.6°F.). After five minutes invert the tubes once, after which avoid agitation. The methylene blue reduction time is the interval between placing the tubes in the water bath at 37°C. and the disappearance of the blue color from the milk. Reduction should be considered complete when four-fifths of the tube has lost its color.

Procedures for Methylene Blue Reduction Test of the Ministry of Health of Great Britain. These are the official procedures for this test in England.²⁴⁷ The other parts of the document are reproduced on pages 336 and 371.

12.⁶⁸ The reliability of the results of the Methylene Blue Test depends upon the strict observance of the directions given below.

Apparatus required.

13. (a) *Methylene Blue*.—Standard methylene blue tablets²⁴⁷ must be used in carrying out the test. From these a standard solution of methylene blue is prepared in the following manner. The tablet is added to 200 ml. of cold sterile glass-distilled water in a sterile flask which is then shaken until the tablet is completely dissolved. After the tablet has dissolved the solution is made up to 800 ml. with cold sterile glass-distilled water and is stored in a cool dark place. If the solution is to be used for longer than a week, evaporation should be prevented by closing the flask with a rubber bung. The solution remains stable in the dark for a considerable time but no stock solution more than two months old should be used.

(b) *Test-Tubes*.—Test-tubes conforming to the British Standard Specification 152/16, nominal 6" x 5/8", having an internal diameter of 13.5 ± 0.5 mm. and an etched mark indicating 10 ml. are to be used. The test-tubes are plugged with cotton wool, or preferably covered with closely-fitting aluminium caps (23 mm. long by 17 mm. broad external diameter). They are sterilised before use in an autoclave at a pressure of 15 lbs. per square inch for 20 minutes or by exposure in a hot air oven to a temperature of 160°C. for two hours. If not to be used directly after sterilisation they should be kept in closed boxes to protect them from dust.

(c) *Rubber stoppers*.—These are supplied so made as to fit the test-tubes. They should be sterilised by immersion in boiling water for five minutes immediately before use.

(d) *Water Bath*.—A metal water bath fitted with a metal cover and containing a test-tube rack is required, in which the test-tubes containing the milk samples can be immersed. The water in the bath must be kept above the level of the milk in the test-tubes and its temperature, which must be between 37°C. and 38°C., should be maintained as nearly uniform as possible by means of a reliable automatic thermo-regulator. The interior of the bath must be completely dark.

(e) *Pipettes*.—1 ml. straight-sided blow-out delivery pipettes should be used for measuring the methylene blue solution, and these should preferably comply with the following specification:—

Overall length.....	300 mm.
External diameter.....	7.5 to 8.5 mm.
Internal diameter.....	2.6 to 3.0 mm.
Graduation.....	1 mark only at 1 ml. level
Distance of graduation from tip.....	140 to 180 mm.
Distance of graduation from top.....	120 to 160 mm.

247. Traces of impurities normally present in methylene blue seriously affect the reliability of the test. It is essential, therefore, that only specially prepared standard methylene blue tablets should be used for this test. The names of manufacturers who supply such tablets may be obtained on application to the Ministry of Health.

The pipettes should be calibrated to deliver 1 ml. of water at 20°C. when the contents are blown out with the tip touching the side of the vessel, three seconds allowed for drainage and the accumulated drop then blown out. No pipette should have an error of more than ± 2 per cent.; that is, the amount delivered should be between 0.980 and 1.020 ml.

The pipettes should be plugged with cotton wool at the upper end, placed in a metal pipette tin or wrapped in Kraft paper and sterilised in a hot air oven at a temperature of 160°C. for 2 hours. The same pipette may be used for adding the methylene blue solution to successive tubes; it may conveniently be operated by a rubber teat.

If large numbers of tubes are being put up, it may be found convenient to add the methylene blue solution by means of an automatic all-glass 1 ml. delivery pipette.

Mixing of Milk in Sample Bottles prior to examination.

14. (a) A sample collected in a special sampling bottle should be treated in the following way. If the bottle is filled to the level of the stopper, it should be inverted 25 times by a rapid rotatory movement of the wrist in order to mix the cream uniformly with the milk. About one quarter of the contents of the bottle should then be poured away and the bottle shaken 25 times, each shake being an up-and-down movement with an excursion of about one foot, the whole shaking lasting about 12 seconds. If the bottle is not completely filled it can be shaken directly in the way just described.

(b) A sample in a sealed bottle or carton should first of all be inverted 25 times by a rapid rotatory movement of the wrist, the cap should be removed with sterile forceps, the whole contents should be poured rapidly into a sterile capped or stoppered bottle of larger capacity, and this should then be shaken in the way described above.

Method of carrying out the Test.

15. Thoroughly mix the sample of milk by inverting and shaking the sample bottle as described above and then pour the milk into a test-tube up to the 10 ml. mark. In doing this the stopper or cap of the bottle should be removed with aseptic precautions, the pouring-lip of the bottle thoroughly flamed with a bunsen burner, the cotton wool plug or the aluminium cap of the test-tube removed, the mouth of the test-tube flamed with a bunsen burner and the milk rapidly poured into the tube up to the 10 ml. mark. In pouring into the tube care should be taken to leave one side of the interior unwetted with milk. 1 ml. of methylene blue solution is then added to the tube from a pipette, care being taken that the pipette does not come into contact with any of the milk in the tube or with the wetted side of the interior of the tube. If this should occur the pipette must be immediately discarded. During delivery the tip of the pipette should be held against the dry side of the tube about $\frac{1}{2}$ to 1 inch above the level of the milk and the methylene blue solution expelled by blowing with the mouth or by means of a teat on the pipette. After the lapse of 3 seconds the solution remaining in the tip of the pipette should be blown out, and the pipette withdrawn. The tube is then closed with a sterile rubber stopper held and inserted by sterile forceps or by the tips of the fingers on its extreme upper end. On no account must the fingers be allowed to come into contact with the mouth of the test-tube or with the end of the stopper which comes into contact with the test-tube. The tube is then inverted slowly once or twice, so that the whole column of contained air rises above the level of the milk, and placed within five minutes in the water bath.

16. With each batch the following control tubes should be put up: (a) 10 ml. of mixed milk²⁴⁸ + 1 ml. of tap water; (b) 10 ml. of mixed milk + 1 ml. of methylene blue solution. Both control tubes (a) and (b) should be fitted with stoppers in the usual way and immersed for 3 minutes in boiling water in order to destroy the natural reducing system present in the milk. Comparison of the experimental tubes with control tube (b) will show when decolourisation is beginning and comparison with control tube (a) will show when it is complete.

248. The milk for the control tubes should consist of a mixture of milks preferably from several producers, so as to have an average fat content and color.

17. The tubes must be inspected at half-hourly intervals. At these inspections (1) any tube that has reached the end point (as defined below) should be removed from the rack, (2) any tube that shows commencing decolourisation should be left until the end point is reached and (3) all other tubes should be *inverted once*.

18. The reduction (decolourisation) of the methylene blue is brought about by the combined action of the micro-organisms and of reducing substances that are naturally present in raw milk. Since these reducing substances are closely bound up with the fat globules, it is very important that the cream should be kept distributed as evenly as possible throughout the milk; if it is allowed to rise and collect at the top, reduction in the main body of the milk will be delayed. It is for this reason that half-hourly inversion of the tubes must be carried out. Any departure from this practice will result in an alteration of the reduction time and consequent invalidation of the result.

19. The milk is to be regarded as decolourised when the whole column of milk is completely decolourised up to within 5 mm. of the surface. The test is then finished. If a trace of colour persists at the bottom of the tube and does not extend upwards for more than 5 mm. it may be ignored. The time (within the prescribed limit) at which decolourisation is observed should be recorded. Where a tube is found not to be decolourised within the prescribed time, the sample satisfies the test.

Precautions in regard to the Test.

20. It is important that the methylene blue solution when not in use should be kept in the dark; it should at no time be exposed to sunlight.

21. The amount of methylene blue required for a day's work should be poured off from the stock bottle into a suitable glass container. On no account should the pipette used for transferring the methylene blue solution to the tubes of milk be introduced into the stock bottle. Moreover, if at any time during the filling of the tubes the methylene blue solution should become contaminated with milk carried into it by a pipette which has inadvertently come into contact with the milk, the methylene blue solution should be immediately discarded and replaced by a fresh supply.

22. It is essential that the interior of the water bath during the progress of the tests should be completely dark, since sunlight, diffused daylight and even artificial light catalyse the reduction of methylene blue. The tubes should not be exposed to direct sunlight during the half-hourly inspections.

23. The design and construction of the water bath including the thermo-regulator must be such as to ensure the maintenance of a uniform temperature of 37°C. to 38°C. during the test.

24. When a number of tests are being carried out it is convenient to place the test-tubes in a rack provided with a metal top to hold them in position so that at the half-hourly intervals all the test-tubes can be simultaneously inverted by merely inverting the rack.

25. The precautions against the adventitious contamination of the milk sample described in the method for carrying out the test must be carefully observed.

26. The sterilisation of the rubber stoppers for the test-tubes and their subsequent satisfactory manipulation can be facilitated by employing a simple rack for holding a large number of rubber stoppers immersed in a suitable vessel of boiling water.

Wilson's² Modified Method for Methylene Blue Reduction Test. After considerable study Wilson proposed a new technic for the reductase test, the main modification of which was inversion of the tubes at half-hour intervals.

It is important to use a standard methylene blue solution. At the moment standardization by chemical means seems impracticable, and the empirical method of comparison of each new batch with an accepted standard is unavoidable. In his own work Wilson used exclusively the standard Barthel-Orla-Jensen methylene blue tablets supplied by Blauenfeldt and Tvede of Copenhagen. One tablet is added to 200 ml. of warm, sterile, glass-distilled water in a flask, which is then shaken till the tablet is completely dissolved. After the solution has cooled down, it is made up to 800 ml. with cold, sterile, distilled

water, and is stored in a cool, dark place, preferably in an icebox. If it is to be used for longer than a week or so, evaporation should be prevented by fitting the flask with a rubber bung. The length of time during which such a solution remains stable has not been determined, but we have observed no significant change within six months in the icebox. The addition of one ml. of this solution to 10 ml. of milk gives a final concentration of methylene blue of approximately 1/300,000.

Test tubes six inches by five-eighths inch external diameter are used, having a 10-ml. mark. The tubes are fitted with cotton-wool plugs and sterilized before use by autoclaving at 15 lb. per sq. in. for 20 minutes, or by exposure in the hot-air oven to a temperature of 160°C.(320°F.) for two hours.

Rubber corks should fit the test tubes. They are "sterilized" by immersion in boiling water for five minutes. Simple racks can be devised for holding large numbers of these corks, narrow ends downward, in a suitable bath of boiling water.

Metal water-baths fitted with metal covers and containing test tube racks are required. The water in the bath is kept above the level of the milk in the tubes, and its temperature is maintained at as constant a level as possible by means of a reliable automatic thermo-regulator. The interior of the bath must be *completely dark*, since both sunlight and artificial light catalyse the reduction of methylene blue. For raw milk the temperature of the water is kept at 37 to 38°C.(98.6 to 100.4°F.); for pasteurized milk an additional bath at 55 or 63°C.(131 or 145.4°F.) may be required.

One-ml. straight-sided, blow-out delivery pipettes, of the type specified, are used for measuring the methylene blue solution. They are plugged with cotton-wool at one end, placed in a metal pipette tin or wrapped in Kraft paper, and sterilized in the hot-air oven for two hours at 160°C. They are operated preferably by a rubber teat. If large numbers of tubes are being put up, an automatic delivery pipette may be used.

Technique for Examination of Raw Milk. Throughout the test it is desirable to employ the usual aseptic precautions. Samples are taken and mixed in the way already described and 10 ml. of milk from each sample are poured into a graduated test tube. In doing this, after the milk has been thoroughly mixed, the disc or cork should be removed with sterile forceps, the pouring lip of the bottle thoroughly flamed, the cotton-wool plug of the test tube removed, the mouth of the test tube flamed in a Bunsen, the milk rapidly poured into the tube up to the mark, and the cotton-wool plug immediately replaced. One ml. of methylene blue solution is then added to each tube by a pipette, care being taken that the pipette does not come into contact with any of the milk in the tube. During delivery the top of the pipette should be held against the side of the tube about one-half to one inch above the level of the milk, and the fluid expelled by means of a teat; after a wait of three seconds, the teat should again be compressed so as to expel the fluid remaining in the tip of the pipette. Each tube is then fitted with a sterile rubber cork picked up by means of a sterile forceps or the extreme tips of the fingers. On no account must the fingers be allowed to come into contact with the mouth of the test tube or the narrow end of the cork. The tube is then inverted slowly once, so that the whole column of air rises above the level of the milk, and placed within five minutes in the water-bath. At half-hour intervals the tubes are inverted once, the color of the milk being noted before inversion. Complete decolorization of the whole column, or complete decolorization up to within five mm. of the surface, is regarded as the end point. Any tube at the time of examination showing obvious signs of reduction should not be inverted, but should be left until the end point as defined is reached. All tubes that are not decolorized within an agreed time may be discarded.

Technique for Examination of Pasteurized Milk. The same technique is employed as for raw milk, but, if desired, duplicate tubes may be put up, one at 37°C., the other at 55 or 63°C. The 37°C. tube is inverted once every half-hour as usual, but the 55 or 63°C. tube, after the preliminary inversion before incubation, is not again inverted, since it is found that the reducing potential established in pasteurized milk by organisms of the thermoduric and thermophilic groups is often insufficient to decolorize methylene blue completely if half-hour aeration is practiced. Any tube not decolorizing methylene blue solution within an agreed time may be discarded.

Several investigators have made comparative studies with the older methods and that of Wilson.² Cinai²⁴⁹ found the modified technic to be recommended in the control of the quality of pasteurized milk. According to Johns²⁰⁹ the accuracy of the test is greatly increased by periodical inversion of the tubes during incubation. In addition, reduction time is generally shortened and decolorization is more uniform, especially with the better grades of milk. It is believed that these advantages more than compensate for the slight inconvenience entailed by this modification. Milks showing similar reduction times by the modified technic of Wilson show wide differences in standard reduction times. These appear to be associated with differences in the degree and rate of creaming. Reduction time is prolonged by approximately 20 per cent with the proposed stronger dye concentration. This is more than compensated for in all but the poorer grades of milk by the shortening of reduction time when inversion is practiced. Thomas²⁵⁰ claimed that the Wilson modification decreased reduction time on the average of five hours. Williams, Davies, and Thomas²⁵¹ reported that the modified technic gave little average difference in reduction time from the old method for samples reducing within 5.5 hours. A very slight average increase in reduction time was obtained with the modified test in the case of the poorer quality samples that reduced within three hours, but there was a marked decrease in reduction time with the better quality samples. Thornton²¹¹ believed the only difference between the standard and the modified technic is that in the modified technic, the tubes are shaken at half-hour intervals. The present evidence does not warrant the replacement of the standard methylene blue reduction test by the modified test since the possible greater accuracy of the latter is offset by greater complexity of technic. Thornton believed that much had to be done yet to make the reductase test entirely reliable.

Results of a comparative study of the old and modified methods were also published by Matuszewski and Supinska.²⁵² The results obtained and their interpretation agreed with theoretical expectations. It was found that deviation in the reduction time, corresponding to a given initial number of bacterial cells, was smaller by the modified than by the old method and that the average time of reduction was shorter. The smaller variation in the reduction time, corresponding to a given number of cells at the beginning of the test, was due probably to a more uniform distribution of the bacteria in the milk following the inversion of the tube. It is suggested that the shortening of the reduction time in the modified test is due to the stimulation of bacterial growth. The average coefficient of multiplication in the old procedure was .66 and in the modified procedure was .885.

Methylene Blue Reduction Test Standards. Several different standards of milk have been proposed; it is probably pertinent to present them. Orla-

249. Ciani. 1939. *Ann. Ig.* 49, 290-308.

250. Thomas. 1938. *Rev. in J. Dairy Sci.* 21, 303.

251. Williams, Davies, and Thomas. 1939. *Welsh J. Agr.* 15, 169-172.

252. Matuszewski and Supinska. 1940. *J. Dairy Res.* 11, 43-50.

Jensen,²⁵³ using Barthel's technic, proposed the following four groups of milk:

(1) Good milk which retains the color seven hours or longer, and which contains at the most 100,000 bacteria per ml.

(2) Fair milk which is discolored between two and seven hours and which, as a rule, has between 100,000 and 3,000,000 bacteria per ml.

(3) Poor milk which is discolored between one-fourth and two hours and which has from 3,000,000 to 20,000,000 bacteria per ml.

(4) Very poor milk which is discolored in less than a quarter hour and contains still more bacteria.

Müller²⁵⁴ said that milk produced in a satisfactory manner required 10 hours for reduction; shorter times were secured with milk in process of delivery to the consumer. Fuller, DePew, and Huggins²⁵⁵ found the reductase test to be a simple and inexpensive method for determining keeping quality. Milk requiring more than five and one-half hours for reduction was satisfactory milk.

Fuller and his colleagues suggested the following classification of milk by means of the reductase test:

Class 1. Good milk, not decolorized in five and one-half hours.

Class 2. Fair milk, decolorized in two and five and one-half hours.

Class 3. Poor milk, decolorized in less than two hours.

de Gaspari and Sangiorgi²⁵⁶ stated that if reduction occurred after two to four hours the milk was useable.

Standard Methods for the Examination of Dairy Products eighth edition, 1941, classified milk into the following groups by means of this test:

Class 1. Excellent, not decolorized in eight hours.

Class 2. Good, decolorized in less than eight hours but not less than six hours.

Class 3. Fair, decolorized in less than six hours but not less than two hours.

Class 4. Poor, decolorized in less than two hours.

THE RESAZURIN TEST

This is a dye reduction test quite like the methylene blue reduction test. It is carried out by adding $\frac{1}{10}$ ml. of a .05-per cent sterile aqueous solution of resazurin to 10 ml. of milk in 20-ml. culture tubes. These tubes are then incubated in the dark at 37°C.(98.6°F.) for one hour, according to instructions of Ramsdell.²⁵⁷ Only one reading is taken according to the original technic, and the test is completed in an hour; the methylene blue test requires over five hours. On the basis of this test milk can be classified into four groups as regards sanitary conditions. Milks from diseased udders and from physiologically abnormal cows have significant effects on the reduction of this indicator, and hence the test aids in their detection. By observing the rate of color change in resazurin-milk mixtures over a period of hours of incubation, much information as to the kind and character of the flora may be obtained. Ramsdell²⁵⁸ later

stated that the resazurin test is as trustworthy as the methylene blue test for evaluating the sanitary condition of milk. The test may be completed in one hour whereas the methylene blue test requires five hours. Resazurin is more sensitive to reducing influence of abnormal milks and consequently more useful than methylene blue in detecting these types of milk. The resazurin test is more effective in detecting very poor milks than the methylene blue test, and with the short incubation period of one hour the flora approximates more closely the initial flora than when longer incubation periods are used, as with the methylene blue test. This opinion was confirmed by Keenan, Barrett, and Rutan²⁵⁹ who stated that more information was gained in one hour's incubation with resazurin than with six hours' incubation with methylene blue. The former test is more sensitive to abnormal and pathological milks than is methylene blue.

Resazurin milk mixtures according to Warner²⁶⁰ change color during incubation from the original blue to a pale violet, then to a rose pink and finally to a colorless state. If resazurin white is taken as the end point, no advantage results in its use over methylene blue. The resazurin violet and resazurin pink reduction times were considerably shorter than the methylene blue chloride reduction times. Warner's opinions in general seemed to be that no great advantage obtained for resazurin over methylene blue. Frayer²⁶¹ subjected samples drawn as aseptically as possible to the resazurin test, the methylene blue reduction test, and plate and cell counts. In the former test one ml. of a .005-per cent solution of resazurin was added to 10 ml. of milk and incubated for one hour at 37°C. In this series the resazurin test correlated poorly with the methylene blue reduction test and hardly at all with the plate count but showed fair correlation with the cell count of the near aseptically drawn samples. It was sensitive to the presence of cells and to the presence and activity of bacteria and very sensitive to strong sunlight or artificial light. Efficient initial cooling of milk retarded resazurin reduction. A supplementary microscope examination appeared necessary if the results of this test were used as a basis for corrective follow-up work. Especial attention was needed to determine the point in the range of the color changes which separates samples needing and not needing further inspection.

Collins, White, Turner, and Rice²⁶² found that uniform results could be secured when the technic was standardized. Good agreement of the resazurin test and the methylene blue reduction test were reported. There was a high agreement between the resazurin test to pink and the methylene blue test in selecting both poor and good quality milks. A resazurin test to pink in three hours is equivalent to a 5.5-hour methylene blue test.

Patrons' milk having a resazurin test to pink in three hours or more was found to have a bacterial count of less than 400,000 per milliliter. Five to six hours indicates less than 100,000 per milliliter.

262. Collins *et al.* 1939. *J. Milk Tech.* 2, 236-244.

The resazurin and methylene blue tests were compared by Davies, Thomas, and Thomas²⁶³ on 575 samples of accredited raw milk, with examination and inversion of the tubes at 30-minute intervals in both tests. The reduction of resazurin to the white stage correlated very well with, but was distinctly slower than, the methylene blue reduction; the average difference was 35 minutes. The reduction of resazurin to purple pink also gave a fair statistical correlation with methylene blue reduction, but about 10 per cent of the samples that reduced resazurin to this stage in one hour failed to reduce methylene blue in seven hours. The resazurin test can be utilized for advisory purposes, particularly when used in conjunction with microscopic examination, and samples that retain the original blue color for one hour at 37°C. (98.6°F.) can be considered satisfactory.

Johns,²⁶⁴ however, believed that the resazurin one-hour test is not as reliable as the methylene blue reduction test. When incubation is continued to the pink stage, however, the accuracy of the test compares favorably with that of the methylene blue test, while the reduction time is shortened. Johns concluded that while the resazurin test is shorter than the methylene blue test, it is not as reliable as the modified methylene blue test, in that it places a larger proportion of high-count milks in the highest grades. If the resazurin test is continued to the pink stage, the comparison with the methylene blue test is favorable. The correlation between the resazurin color and the cell count was found to be much poorer with market milk than with individual quarter samples. Finally, it was concluded that further research concerning resazurin and its reactions in milk must be undertaken before the use of the test in milk control will be comparable to that of methylene blue tests. Johns and Howson²⁶⁵ later advised a "triple reading" resazurin test which they said gave better results. They were more satisfied where the color number of each sample is recorded hourly. In view of the fact that this could not be done on a large number of samples Johns and Howson attempted to devise a simpler method which would combine the sensitivity of the "one-hour" test for abnormal milks with the greater accuracy of the "pink end point" for bacteria. Such a technic was proposed.

An incubation temperature of 18°C. (64.4°F.) instead of 37°C. was recommended by Davis and Watson.²⁶⁶ The recommended time was three hours instead of the one hour at 37°C. Various reasons were offered to support this suggestion.

Dye for the Resazurin Test. As has been the case with most tests in which dye is used, attention must be given to the brand of dye used. Nelson²⁶⁷ tested four brands and found only two to be satisfactory. Nelson, therefore, believed that resazurin would have to be standardized before the test can be generally adopted.

Ramsdell²⁵⁷ recommended a .05-per cent solution of the dye. Collins *et al.* did not find this strength sufficiently accurate when speed is required and he followed the suggestion of Moldavan²⁶⁸ that one ml. of a .005-per cent solution be used. Collins and his colleagues also found that an intermediate pink color could be read uniformly by various investigators. Consequently, a pronounced pink but not a vivid pink was used as the end point. Possibility of resazurin tablets and solutions containing significant numbers of bacteria was pointed out by Thomas and Thomas.²⁶⁹ They recommended plating of the solutions occasionally. Advantages of storing the solutions in the refrigerator were also mentioned.

Collin's et al.²²⁶ Technic for the Resazurin Test. Ten-ml. portions of the milk under examination are placed in sterile test tubes. The tubes are then brought to a temperature of 37°C. (98.6°F.) in a water bath for five minutes. One ml. of the fresh .005-per cent resazurin dye is then added by means of a 10-ml. pipette and the sample mixed by inverting. The tubes are then incubated at 37°C. either in an incubator or water bath. They are read in medium light but away from direct or reflected sunlight.

Application of Resazurin Test for Determining the Quality of Pasteurized Cream. According to Chilson and Collins²⁷⁰ the resazurin test is a satisfactory and rapid criterion of keeping quality of cream. They did not find it always reliable for picking out high-count cream which had been stored at 4.4°C. (40°F.) for four or more days. A six-hour reduction time was said to be a criterion of high quality in pasteurized cream.

A valuable resumé of the resazurin test was prepared by Davis.²⁷¹ He discussed many problems which must be considered by those who use this test for grading milk.

CHAPTER 7

PASTEURIZATION OF MILK

Few efforts to protect the public health have been so uniformly accepted by health officials and the consumer as milk pasteurization. Practically all milk in the large urban centers is pasteurized with possible exception of some "certified" milk; much of it is now pasteurized. Milk-borne epidemics have been greatly reduced in number. Microbiological problems of the process concern mainly destruction of bacteria in milk which cause disease and investigation of types which survive.

The Milk Ordinance and Code recommended by the United States Public Health Service¹ defines pasteurization as follows:

"The terms 'pasteurization,' 'pasteurized,' and similar terms shall be taken to refer to the process of heating every particle of milk or milk products to at least 143°F., and holding at such temperature for at least 30 minutes, or to at least 160°F., and holding at such temperature for at least 15 seconds, in approved and properly operated equipment; provided that nothing contained in this definition shall be construed as dis-barring any other process which has been demonstrated to be equally efficient and is approved by the State health authority."

Many states have adopted virtually the same definition. The State of Illinois has adopted this same definition.² Frank,³ who supervised preparation of the United States Public Health Milk Ordinance and Code, believed that an effective and practical definition of pasteurization should satisfy the following criteria: It must be effective with respect to the killing of any pathogens in milk and be practical with respect to enforcement by the health official, and its application by the dairy industry. Frank believed that these objects were attained in the standard code.

Perhaps other factors than merely destruction of pathogenic bacteria may be considered in the future for determining the temperature which shall be used for pasteurization of milk. When cream volume, phosphatase test, destruction of *Escherichia coli*, rennet coagulation time, and other factors were considered by Holland and Dahlberg⁴ 76.7° (170°F.) seemed to be quite promising as a new standard for pasteurization.

Objections to Pasteurization of Milk. While many objections were once raised against milk pasteurization it is generally accepted today by the public. The few who question the process have not secured all of the facts or are unwilling to face them. Some of the more important objections, are as follows:

1. *Increases Cost.* Whether this argument against pasteurization has weight depends on the value placed on other factors. Any procedure which

3. Frank. 1930. Amer. J. Pub. Health 20, 1105-1119.

4. Holland and Dahlberg. 1941. J. Dairy Sci. 24, A 103-104.

has for its object increased safety of foods is probably justified. Furthermore, any effort which tends to protect the unsuspecting portion of the population, the children, is justified at significantly increased cost.

2. *May Conceal Inferiority.* While this is possible to a certain extent, it is a criticism which does not have much weight. The dirt test, for instance, may be applied to pasteurized milk as well as to raw milk in order to determine cleanliness. It is possible that old milk could thus be made safe, but the enforcement of certain standards for milk which is to be pasteurized prevents it. Most cities, by means of efficient inspection, are able to enforce the required procedures to maintain a good raw milk. When such milk is pasteurized, a double attempt has been made to make it safer.

3. *Interferes With Cream Rising and Whipping.* Considerable work has been done to determine just what chemical changes are brought about in milk by pasteurization. Rupp⁵ reported that milk pasteurized by the holder process at 62.8°C. (145°F.) underwent no appreciable chemical change. He found that the acidity of pasteurized milk was slightly diminished. However, pasteurization by the holder process at 65.6°C. (150°F.) did cause changes in the milk. Dutcher⁶ has confirmed this.

Results of experiments by Kilbourne⁷ indicated that when milk was cleaned by a centrifugal clarifier the volume of cream in the milk is reduced from two to three per cent. It was evident that volume of cream in bottled milk is influenced by various factors, among which are temperature to which it is heated, length of time it is held at the high temperature, temperature of the heating medium with which it comes in contact during the heating process, clarification, type of apparatus used, and amount of agitation to which it is subjected, especially when hot. This last factor appears to be one of the most important. It is believed that, under the most favorable circumstances, heating to 62.8°C. (145°F.) and holding for 30 minutes may be done without any injurious effect upon the cream line, but it has been deemed best to reduce the required temperature to 61.1°C. (142°F.) in order to allow for uncontrollable factors which may tend to offset the volume of cream.

The layer of cream on milk in the bottle is important because the consumer uses it as an index of the richness of the milk. Harding⁸ was especially concerned with the effect of the new higher temperatures which were being advocated. While 60 to 62.8°C. (140 to 145°F.) for 30 minutes was generally recognized as the proper temperature, there was a growing demand that 62.8°C. (145°F.) be accepted as the minimum. Harding found that the volume of cream on bottled pasteurized milk was measurably less when temperature of pasteurization was 61.1 to 62.2°C. (142 to 144°F.). Higher temperatures caused greater decreases in cream volume; at 62.8°C. (145°F.) it amounted to slightly more than 10 per cent by volume; at 63.3°C. (146°F.), it was 16.6 per cent; and at 64.4°C. (148°F.), decrease was about 40 per cent. Harding's method of measuring this was to fill round-

bottom test tubes one-half inch in diameter to a depth of eight inches with the milk. The tubes were then cooled and kept at 4.4°C.(40°F.) for 24 hours. The depth of the cream layer was measured in millimeters, each millimeter of cream representing .5 per cent of cream by volume. Marcussen⁹ found that the average volume of cream on milk pasteurized at 62.8°C.(145°F.) was 13.325 per cent less than the average volume of cream on the same milk, pasteurized at 61.1°C.(142°F.). This subject was also studied by North *et al.*¹⁰ in extensive experiments at Endicott, N. Y. They reported, in general, that with the standard holding period of 30 minutes a temperature below 62.8°C.(145°F.) during the holding period was without noticeable effect upon the cream volume. The effect first became noticeable at about 63.3°C.(146°F.) and of practical importance at about 63.8 to 64.4°C.(147 to 148°F.). Loss of cream line does not mean loss of fat. The fat is in the bottle, but does not come to the top, owing to dispersion of fat droplets. The same question was studied by Holland and Dahlberg¹¹ over the range in temperature from 60°C.(140°F.) to 79.4°C.(175°F.). A semilogarithmic relationship was found to exist between time and temperature in the case of cream volume, inactivation of phosphatase, and destruction of *Escherichia coli*. Much of the information on questions such as this one, is based on the old methods of pasteurization. Introduction of the newer methods of high temperature-short time methods made it necessary to review the subject to determine how they affected the cream line.

Results of experiments by Dahlberg and Marquardt¹² revealed that maximum cream layer was secured by heating to slightly less than 62.8°C.(145°F.) for a holding period of 30 minutes. Cooling should be promptly accomplished at 4.4°C.(40°F.) or below. The rate of cooling was found to influence creaming, whether slow or rapid creaming obtained. Cream-line destruction was shown by Supplee and Jensen¹³ to vary from six to 20 per cent through the temperature range of 71.1°C.(160°F.) to 82.2°C.(180°F.) and to increase rapidly thereafter for each degree rise in temperature.

4. *Modifies Taste.* Taste is undoubtedly modified by pasteurization. However, one must decide whether he would prefer to use a food product which is safe, although some of the methods which were employed to make it safe may have slightly altered the taste. Taste is a matter of education, anyway. The longer pasteurized milk is used, the less weight this objection will have. If pasteurized milk is used from childhood the taste of it will be the normal. Hammer and Hauser¹⁴ prepared a table of the statements of various authorities on the effect of heat on the taste of milk.

5. *Less Wholesome.* This was a general criticism in early days when pasteurization was introduced. It was said that pasteurized milk had no

“life.” When vitamins were discovered, some basis existed for this contention and many investigations were carried out to determine whether they were destroyed. Under any conditions the vitamin content of milk is variable and is influenced by the season of the year, the food of the cow, and the animal herself. Consequently it is a matter of no great concern whether pasteurization destroys vitamins. The literature on this question is voluminous and will not be reviewed in this book.

Results of comparative experiments in which raw and pasteurized milks were fed to animals have consistently shown that animals gain weight and develop just as well on the latter as on the former. Wilson¹⁵ and his colleagues observed this with calves.

Finally, mention may be made of an analysis of results of a survey by Frank *et al.*¹⁶ of over 3,700 children under six years of age as to weight, diet, and health history. This survey was conducted in over 39 cities in 10 states and involved two groups of children using raw and pasteurized milk. No information was gathered which reflected on the pasteurization process. In fact, a higher incidence of scarlet fever, diphtheria, intestinal disturbances, and rickets was observed in the children on raw milk.

6. *Pasteurized Milk Putrefies Rather Than Sours.* This was an early belief which has since been disproven. It was based on the fact that the lactic acid-forming bacteria were nonsporeformers and therefore were susceptible to heat. The sporeforming bacteria, which are quite proteolytic, survive to peptonize the milk proteins. Products of this were supposed to be the causes of severe intestinal upsets. The explanation seemed to be logical but was soon proved false. As shown a little later in this chapter, lactic acid-producing bacteria can survive pasteurization. Despite results of many different experiments, these issues are constantly raised; for instance, Fearis¹⁷ suggested that more inquiry is necessary as to the possible detrimental effects of the destruction of the lactic acid bacilli. He suggested possible multiplication of pathogenic bacteria freed from the restraining acid production, the absence of destruction of aerobic sporing organisms, such as *Bacillus subtilis* alleged to cause toxemia in infants, and the loss of oxygen in the milk from pasteurization.

Advantages of Pasteurization. Years of research and experience have furnished much evidence to support pasteurization of milk. All of the objections which have been or may be raised against the process may be met by one—that it makes milk safe.

1. *Makes Milk Safe.* Pasteurization destroys pathogenic bacteria in milk. Need for some method to rid milk of *Mycobacterium tuberculosis* caused health officers to resort to heating of the milk. Later as other pathogenic bacteria were found to occur in milk, it was found that they, also, were destroyed. Once these bacteria are destroyed, the pasteurized milk must be guarded against reinfection. The bacteriological evidence on

17. Fearis. 1935. *Lancet*, April 27, 1935, 1015-1016.

this entire problem has been discussed in a companion volume, "Food Borne Infections and Intoxications."¹⁸

Epidemiological evidence is available in abundance to support the statement that pasteurization destroys pathogenic bacteria in milk. Such diseases as typhoid fever and diphtheria, which were once scourges, have been greatly reduced. Milk pasteurization has had an important part in reducing these diseases. The former could probably be entirely stamped out were it not for the human carrier.

2. *Lowers Infant Mortality.* It is difficult to collect information on this point. It would also be difficult to plan an experiment and consequently, conclusions must be drawn from groups of infants which have received raw and pasteurized milk. The argument that milk pasteurization reduces infant mortality has been the center of much discussion. Some argument has arisen about causation of rickets or rachitis. Other argument has involved the changes brought about in the stomach by heated milk and raw milk. Brennemann¹⁹ gave important data on this subject. He stated that raw milk was much more liable to cause the formation of indigestible hard curds in the stomach than pasteurized milk.

The results of feeding raw and pasteurized milk to infants was studied by Park and Holt²⁰ in New York City, who found that raw milk with a low bacterial content caused more cases of illness than the same milk given after pasteurization.

3. *Prolongs Keeping Quality.* While the real purpose of pasteurization of milk is not to make it keep longer, the heating involved does reduce the general bacterial population. This results in a product which will keep for a much longer time, especially when it is refrigerated. This is an important practical result of pasteurization. Prolonged keeping quality of pasteurized milk is an advantage gained with pasteurization even though it is not the original reason.

Pasteurization of Milk in the Final Package. After milk has been made safe by heat, the next problem is to keep it so by preventing reinfection. While opportunities for reinfection after bulk pasteurization are remote, they are possible as shown by Bray.²¹ Consequently, possibility of pasteurization in the bottle has been studied. Carter,²² North,²³ and Ayers and Johnson²⁴ all observed satisfactory reductions in bacterial content after pasteurization in the bottle. North used both submergence of the bottles and the shower-bath type of pasteurizer. Special caps are necessary and the tops of the bottles must be sound, else it will be difficult to secure tight seals. Carter found that a temperature of 65.6°C. (150°F.) for 30 minutes was best. Ayers and Johnson reported that a temperature of 62.8°C. (145°F.) for 30 minutes caused satisfactory bacterial reductions, but that bottles should be steamed for at least two minutes before being filled with

milk. When milk at an initial temperature of 10°C.(50°F.) was heated in bottles without agitation in water at about 62.8°C.(145°F.), the temperature of the milk in the top of the bottle reached 60°C.(140°F.) in about nine minutes before that in the bottom. Hammer and Hauser¹⁴ found that milk pasteurized in bottles for 50 minutes at 62.8°C.(145°F.) was satisfactory. As temperatures higher than those just mentioned were used, the milk became less satisfactory.

Successful results were also reported by Weigmann,²⁵ Judkins and Downs,²⁶ Kufferath,²⁷ and Wright²⁸ as far as bacterial reduction is concerned. However, the difficulties of the process were pointed out. It is not only necessary to heat every particle of the milk to pasteurization temperature, but it is equally as important to cool the milk promptly. If it is not cooled, it may remain so long at incubation temperatures that bacteria will grow. Despite the advantages of bottle pasteurization, it has not been used to any extent.

Contamination after pasteurization must be prevented, as Bulmer²⁹ has pointed out. Pasteurization in the final package might make it more unlikely.

High Temperature-Short Time (Quick-Time) Pasteurization of Milk. This method involves heating milk to a higher temperature in shorter time than used in other methods. Most milk ordinances which permit flash or "high-short" pasteurization of milk place a minimum temperature at 71.1°C.(160°F.) for 15 seconds. This is the minimum stated in the United States Public Health Service Milk Ordinance and Code.¹ Higher temperatures are used for some other products. Flash pasteurization was not acceptable at one time to health officers because it was believed to be less efficient than the holding method. After much research, which has revealed that "high-short" pasteurized milk is safe, it is more generally acceptable. It has been accepted by committees of the American Public Health Association. Shrader³⁰ has reviewed in a fine report the bacteriological aspects of "high-short" pasteurization of milk. Supplee and Jensen¹³ found that the dominant lethal factor in this method is temperature. The lethal value of elevated temperatures at a constant time of only a few seconds increases in a straight-line relationship up to 82.2 to 85°C.(180 to 185°F.) efficiency falling off rapidly at higher temperatures.

Yale and Breed³¹ reported that high temperature-short time pasteurization was not as conducive to high counts of thermophilic bacteria as the long-time machines. Yale later reported results of experiments carried out in co-operation with the New York State Department of Health on the bacteria found in milk before and after pasteurization by a short-time pasteurizer at 71°C.(160°F.) for 15 seconds and after pasteurization by

the holder process at 61.7°C. (143°F.) for 30 minutes. Samples of the same milk were pasteurized under like conditions in the laboratory. The bacteriological counts determined on standard nutrient agar plates showed that pasteurization by the holder process was slightly more effective, the average count immediately following pasteurization being 17,200 per milliliter for the former as compared with 20,600 per milliliter for the latter. It was also of interest that the laboratory pasteurization methods gave approximately 50 per cent lower bacterial counts than when the milk was pasteurized under commercial conditions. Holding the milk for 24 hours 40 to 45°C. (4.4 to 7.2°F.) reduced the count of bottled pasteurized milk from 22,800 at the time of pasteurizing to 9,600 per milliliter at the end of the storage period. With the continued operation of the high-temperature pasteurizer the counts were increased from 22,000 for the first 25 minutes of operation to 34,000 after 30 to 90 minutes of operation. Foam collected from the layer on the surface of the milk of the pasteurizer yielded plate counts from two to 11 times higher than corresponding raw-milk samples. Yale³² concluded from all of this work that high temperature-short time pasteurization produced as good a bottle of milk as did the 30-minute holding pasteurization, a conclusion in which Parfitt³³ later concurred.

The bacteriological problems relating to "high-short" pasteurization have been amply studied. A comprehensive investigation on high temperature-short time pasteurization was made by Mattick and Hiscox.³⁴ In their first series an old-type plant was used and the tabulated findings suggested that at the lowest tested temperature 70.4°C. (158°F.) and holding time of about 11.5 seconds tubercle bacilli in milk are killed, but that with this holding time if the temperature is below 71°C. (160°F.) the phosphatase test is positive, i.e., gives figures above 2.3 units. The second series with a modern plant of stainless-steel pressed plates showed still more definitely the high phosphatase figures at 71°C. (160°F.) or even 72.1°C. (162°F.) without holding. With even a few seconds holding, e.g., in a Stassane machine heated to 72.8 to 74.9°C. (163.4 to 167.2°F.) and held for 3.4 seconds, the phosphate test was negative. It was still negative at 66.9°C. (151.6°F.) but became positive at temperatures below this. The authors concluded that under practical conditions in a good plant a temperature of 72.1°C. (162°F.) for 15 seconds is satisfactory, offers a good margin of safety, and does not damage the cream line. Like approved "holder" types, accurate working is still somewhat at the mercy of the operator and indeed with high-temperature apparatus this is even more the case. Adequate control is especially necessary. They considered that this type of pasteurization should be permitted for pasteurizing by-products (skim milk, whey, etc.) under the Tuberculosis (Arrested Herds) Scheme 1938, and that there is also a case for serious consideration of "high temperature-short time" pasteurization as an official method alternative to the holder

process. A summary of information, especially bacteriological, was prepared by Dotterer³⁵ who believed that it could be accepted.

The Committee on Milk Supply of the Public Health Engineering Section of the American Public Health Association,³⁶ and the Committee on Milk Sanitation of the Conference of State Sanitary Engineers jointly considered the problems involved in high temperature-short time pasteurization. This method has not been approved because there seemed to be little assurance that every particle of milk will be heated to the required lethal temperature. The slightest lack of attention on the part of the operator might make it possible for improperly pasteurized milk to be supplied to the consumer. Development of a method which involved holding the milk for a short time at the lethal temperature, seemed to avoid some of the objections. Two types of these pasteurizers were in commercial use; in one the heating medium was hot water and in the other it was electricity. The first of the latter type was marketed under the name "Electropure." In view of the fact that this was quite a new pasteurizer, it was subjected to numerous and repeated tests by public-health authorities and private agencies before it was accepted. Some of the results of these investigations are presented below. These committees found this apparatus satisfactory, provided, certain recommendations which they prescribed were heeded. These were mainly mechanical and need not be listed here.

Various types of high temperature-short time pasteurizers were tested by joint committees of the American Public Health Association. These types were approved when certain recommendations of these committees were heeded. In the next Yearbook these same committees reported the York Plate pasteurizer to be efficient in destroying *Mycobacterium tuberculosis* and hemolytic streptococci. The results revealed an ample margin of safety in time and temperature when milk is heated to not less than 71.1°C.(160°F.) for not less than 15 seconds. The hemolytic streptococci survived heating without holding better than *Mycobacterium tuberculosis*. The bacteriological efficiencies of the method were reported at some length by Hileman and Leber³⁷ who compared the results with those secured by the older conventional methods.

Several special methods or pieces of apparatus have been developed. One of these, known as the Grindrod sterilizer, involved superheating milk under pressure with a finely divided jet of steam. Its efficiency was studied by Hucker and Hucker,³⁸ using milk cultures of pure strains of organisms of known heat resistance as well as uninoculated milk which had been allowed to develop a heat-resistant flora; 110°C.(230°F.) for one to two minutes eliminated all non-thermophilic organisms; thermophilic heat-resistant types were materially reduced at this temperature, but 115.5°C.(240°F.) for three to five minutes was required to free milk from them. The process may be adaptable to condensing and drying of milk. Its use

in the market-milk field may be confined to semitropical and tropical conditions where sterility is essential. This method destroys the cream line, gives a slight "boiled" flavor, and at the high temperature used there is a slight precipitation of albumin. Its advantages include the possibility of completely sterilizing milk, the rapidity of the process, and the removal of, in certain cases, the odors and flavors.

Another method of high temperature-short time pasteurization is termed stassanization which was compared to the holder method by Critien and Walker.³⁹ The stassanization temperature used for comparison is 75°C. (167°F.) with exposure for 16 to 22 seconds. No experiments are recorded, the authors apparently relying upon statements in various papers on the subject. They conclude that both methods are reliable as regards destruction of pathogenic bacteria but decide in favor of stassanization on the grounds of the slightly less alteration to the milk under this process and its greater economic advantages. They are careful to point out that this conclusion refers to the type of milk they have to deal with, i.e., goat's milk with few bacteria.

Destruction of pathogenic bacteria by the high temperature-short time method of pasteurization at 71.1°C.(160°F.) seems now to be well established. Workman⁴⁰ found this to be the case with many strains of pathogens causing the more important milk-borne diseases. Van Oijen⁴¹ found that *Mycobacterium tuberculosis* was satisfactorily destroyed by the process discussed above as stassanization.

Dahlberg, Holland, and Miner^{41a} successfully pasteurized milk by the "quick-time" method at 80.8°C.(177.5°F.) to 76.1°C.(169°F.) with the time interval above 60°C.(140°F.) varying from five to 24 seconds. Comparable pasteurization results were secured by the following:

Time above 60°C.(140°F.)	Highest temperature
5 seconds	81°C.(177.5°F.)
6 seconds	79.4°C.(175°F.)
12 seconds	76.6°C.(170°F.)
24 seconds	76.1°C.(169°F.)

Pasteurization by Electricity. Many attempts have been made to pasteurize milk by electricity. In 1894 Mason and others heated milk to 75.8°C. (168°F.), and at the same time subjected it to the effects of an electric current. Experiments at the University of Liverpool⁴² showed that by means of specially constructed apparatus, not only could milk be sterilized, but that *Mycobacterium tuberculosis* therein could be destroyed. Satisfactory results were also reported by the use of a high tension current with a short period of exposure in New South Wales.⁴³ The advantages of not overheating, no coagulation, and the ability to use continuous flow, were reported. Members of the coliform group were destroyed. There was also

a substantial reduction in all forms. No changes were induced in the milk. The same effects were reported by Kershaw.⁴⁴ In two cases, tuberculous milk was rendered free from living tuberculosis organisms and was regarded as a safe food. Lewis⁴⁵ reported that electricity was a satisfactory sterilizing agent for milk. The total bacterial count was reduced, *Escherichia coli* killed, and the milk was rendered noninfectious with organisms of tuberculosis. The University of Liverpool experiments were reported in full by Beattie and Lewis,⁴⁶ who carried out experiments for two purposes, to investigate the possibility of using the electric current as a sterilizing agent, and, if successful, to adapt it to large scale practice. They gave special consideration to the destruction of *Mycobacterium tuberculosis* and *Escherichia coli* and its allies. In the earlier experiments, direct current was used; it gave unsatisfactory results. There was evidence of destruction of bacteria, but the chemical changes in the milk were so pronounced that use of the direct current had to be given up. The initial experiments with the alternating current were sufficiently successful to justify further study. The details of the investigation may be left to a perusal of the original report. Beattie and Lewis stated that milk could be rendered free of *Escherichia coli* and *Mycobacterium tuberculosis* by the electrical method without raising the temperature higher than 63 to 64°C. They believed that this temperature effect was of too short duration to be the principal factor in explaining the action of the electric current. They observed a percentage reduction of 99.93 per cent, which caused a prolonged keeping quality. So little chemical change was caused that Beattie and Lewis referred to milk treated by electricity in their apparatus as "raw milk" free from pathogenic bacteria.

Anderson and Finkelstein⁴⁷ studied a patented electric pasteurizing apparatus installed at Camp Meade, Md. The milk was exposed to an alternating current of 2,300 volts. After being previously heated to 40°C. (104°F.), it was passed in rapid succession through four porcelain cups of about 200 ml. capacity, in each of which it came in contact with two electrodes and completed the circuit. The resistance of the milk to the passage of the electric current generated sufficient heat in about 20 seconds to raise the temperature to 70°C. (158°F.). A satisfactory reduction in the number of bacteria was noted when the machine was operated properly. The final product was equal to milk designated as Grade B pasteurized milk, and was often equal to Grade A milk sold in New York City. Practically all of the coliform organisms were destroyed. Treated milk kept well at from 5 to 10°C. (41 to 50°F.) for five days. The machine raised the temperature to about 30°C. (86°F.), irrespective of the initial temperature. Anderson and Finkelstein concluded that the heat generated was the active agent and not the current itself, because the bacterial content was not reduced when the initial temperature was below 25°C. (77°F.). Beattie

and Lewis⁴⁶ still were of the opinion that the electricity itself and not the heat was the active agent in electrical pasteurization. Milk which was heavily seeded with *Mycobacterium tuberculosis*, when passed through the tube and treated with sufficient electric current to raise the temperature to 62 to 64°C. (143.6 to 147.2°F.), failed to infect guinea pigs; however, tuberculosis milk raised to but 60 or 62°C. (140 or 143.6°F.) produced slight infections. Generalized tuberculosis appeared in guinea pigs inoculated before treatment.

Milk was heated by Collumbein⁴⁸ to pasteurization temperatures by the resistance offered to a current of 3,000 volts. The count was reduced to a maximum of 25,000 per ml. As has been indicated in other fields of applied bacteriology, percentage reductions are meaningless, since with a 99.9 per cent reduction, the treated milk may have a high count, or contain pathogens.

Another study of the "electropure" pasteurizer was made by Robison.⁴⁹ This investigator stated that the following conditions were involved in the ideal process of pasteurizing milk:

1. Preservation of the cream rising phenomenon, or cream line.
2. Retention of the natural taste.
3. Preservation of the activity of natural vitamins.
4. Prolongation of the keeping quality.
5. Great reduction of total number of bacteria.
6. Destruction of pathogenic microorganisms.

The "Electropurifier" was put to a severe test by a milk heavily inoculated with *Mycobacterium tuberculosis* (5,000 cells per ml.). The results were practically perfect. One pig developed tuberculosis when given the infected "purified" milk, but it was stated that there was evidence of infection before the experiment started. As Robison stated, one would hardly ever expect to have a milk sample with 5,000 tubercle bacteria per ml.

On September 10, 1925, a dairy in Pittsburgh (Irwin, *et al.*⁵⁰) requested permission of the Pennsylvania Department of Health to use the Electropure Process of milk treatment. The secretary of health appointed a committee to investigate the efficiency of the process, and on April 13, 1926, the committee report was presented. This report gave a description of the apparatus used and a record of the results obtained in the experimental plant. Milk inoculated with *Corynebacterium diphtheriae*, *Eberthella typhosa*, hemolytic streptococcus, *Mycobacterium tuberculosis* (bovine and human), *Escherichia coli*, and *Aerobacter aerogenes* was used in measuring the efficiency of the process. Temperatures of 65.6°C. (150°F.), 68°C. (155°F.), and 71°C. (160°F.) were used, and the retention period in the electric heater varied between eight and 10 seconds. It was their opinion, based on results of experimental work, that the process was a reasonably safe method for pasteurization of milk, and merited a thorough trial under commercial conditions, as well as continued investigation as to its efficiency in destroying the tubercle bacillus.

50. Irwin *et al.* 1927. Penn. Assoc. Dairy & Milk Insp., 3rd Ann. Rpt. 143-146.

On December 21, 1926, the committee submitted its final report. This report gave the results of experimental work with *Escherichia coli* and *Mycobacterium tuberculosis*. Samples of treated and untreated milk were collected to determine the total number of bacteria and of *Escherichia coli* present. Samples were also collected from a dairy to show the results obtained by heating milk to 62.8°C. (145°F.) for 30 minutes in one type of horizontal-coil vat pasteurizer. It was the conclusion of the committee that the results of the work set forth in the final report confirmed the opinion given in the former report, namely, that the method known as the Electropure Process was a reasonably safe method for the pasteurization of milk. The bacteriological results obtained in a study of the process under commercial conditions confirm this opinion and supported the findings obtained under experimental conditions.

Prescott⁵¹ also had an opportunity to observe electric pasteurization over about a year's time. Milk was pumped through the apparatus at such a speed that a 220-volt alternating 60-cycle current raised the temperature to 70 to 71.1°C. (158 to 160°F.) and at that speed 12 seconds were required to pass the milk through the treating chamber. The results showed great uniformity of treatment, normal taste and cream volume, and excellent keeping quality. The reduction of bacteria was highly efficient. No colon or tubercle bacilli were found among the surviving types.

The construction and operation of the "electropurifier," mentioned above, was described by Bailey.⁵² The electric heater or, as it is called, the "electropurifier," contains an oblong chamber approximately three by four inches in cross section and 32 inches high, two opposite sides being of carbon and separated from each other by sides of hard rubber. There is an electrical connection on each of the carbon sides of the box, and a 60-cycle, 220-volt current is used in heating. Milk enters the bottom of the electric chamber and acts as a conductor for the current between the sides of the box. A temperature of 71.1°C. (160°F.) is used, and the time of passage of the milk through this machine is approximately 10 seconds. An automatic temperature control regulates the temperature of the milk leaving the heater by controlling the speed of the pump and, consequently, the rate of flow of milk, the electrical input to the machine being constant. Statements are made that there is no change in the flavor of the milk as it goes through the machine, and that a phenomenal bactericidal efficiency is obtained. It is said that no attempt is made to explain the action as there are different opinions regarding it, the various opinions being listed as heat alone, heat and electricity, and electrochemical action; the company believed that it is a "heat-plus" proposition.

Van Leersum⁵³ also found that the electric current was germicidal. The high frequency current was just as germicidal, whether carbon or copper electrodes were used. Demeter⁵⁴ reported the effectiveness of

electric pasteurization. Richter and Wendt⁵⁵ compared the amount of direct flow through two types of flash pasteurizers. The results showed that in one type of pasteurizer, which was cylindrical in shape, portions of the milk passed through in a few seconds, while other portions remained for as long as four minutes. The top of the other type of pasteurizer was larger in diameter than the bottom. The maximum and minimum time required for milk to go through this type was 70 and 15 seconds, respectively. In the latter type, the destruction of *Escherichia coli* was very complete. At the California Agricultural Experiment Station the Electropure process was reported to yield more effective destruction of bacteria in ice cream mix than the holder method. Carpenter⁵⁶ stated that the electrical method freed milk of viable tubercle bacilli. The milk which was used was heavily inoculated with *Mycobacterium tuberculosis* and contained from 2,400,000 to 4,000,000 cells per ml. According to Yale,⁵⁷ the high temperature, 72.2 to 73.3°C. (162 to 164°F.), attained in the Electropure pasteurizer caused a marked reduction in the thermophilic bacteria in milk. Devereux⁵⁸ reported the Electropurifier to be very efficient when operated at 71.1°C. (160°F.). This temperature was found to be reached when the milk had traveled about two-thirds of the distance, having been exposed to this temperature only 15 to 20 seconds. Milk inoculated with sporeforming bacteria, including *Bacillus anthracis*, was passed through the machine with a reduction of from 71.5 to 99.9 per cent of the spores. Tubes containing the same milk treated in a manner similar to steam sterilization showed a reduction in the sporeforming organisms of 0 to 13 per cent. Gelpi and Devereux⁵⁹ reported that the Electropure process gave greater destruction of spores of bacteria than pasteurization at 62.8°C. (143.8°F.). A series of commercial milk samples were treated by Stabler⁶⁰ in the Electropure apparatus and compared with specimens of the same milk treated in the laboratory at 62°C. (143.6°F.) for 30 minutes.

The Electropure laboratory unit was sterilized after each run in a manner not practicable under commercial conditions. The milk was electrically heated for five minutes. Under these rather artificial conditions the bacterial count for milk held at 62°C. (143.6°F.) for 30 minutes was practically identical (97.2 to 97.7 per cent reduction) with that with the Electropure unit heating the milk to 73°C. (163.4°F.). By both methods the surviving organisms included streptococci, sarcinae and micrococci, aerobic spore bearing bacilli and anaerobes, and no definite differences between the two methods were disclosed. No true *Escherichia coli* occurred in milk pasteurized by either method. When the electric temperature was 62°C. (143.6°F.) only a reduction of 98.3 per cent of organisms was obtained. Electrical pasteurization diminished the rate at which cream rises while not affecting the total cream content. Stabler's results were con-

cerned mainly with percentage reduction in bacterial numbers and to some extent with types. The effect of the process on pathogenic bacteria was not studied.

Holmquist⁶¹ tested the Electropure process for the N. Y. State Department of Public Health in co-operation with the United States Public Health Service and the Department of Health of New York City. These tests extended over two weeks and were as stringent as they could be made. It was found from these tests that under normal operating conditions milk rendered highly infectious with *Mycobacterium tuberculosis* when heated in the Electropure apparatus operated at a mean temperature of 67.2°C. (153.9°F.) and held for a period of 12.4 seconds, was rendered noninfectious to guinea pigs. The pump-stop temperature during that run was 65.6°C. (150°F.). The next lower pump-stop temperature at which the apparatus was tested was 58.4°C. (138°F.). In other words, there were no test runs between the pump-stop temperature of 65.6°C. (150°F.) and 58.4°C. (138°F.).

These tests demonstrated to the satisfaction of the Public Health Council of the State of New York that this high temperature-short time process of pasteurization was equally as efficient, dependable, and safe as the so-called holding process of pasteurization, and it was approved by the Council and the State Department of Health on the condition that every particle of milk be heated to a temperature of not less than 71°C. (160°F.) and held at that temperature for not less than 20 seconds. This condition provided factors of safety of at least 3.3°C. (6.1°F.) and 7.6 seconds. Although this temperature factor of safety is approximately that generally accepted as satisfactory for the holding process of pasteurization, the time factor is negligible when compared with that required for the holding process. When dealing with temperatures around 71.1°C. (160°F.), however, seconds count more than minutes at temperatures from 61.1°C. (142°F.) to 62.78°C. (145°F.). The time factor has not received as much study as it should in this method of pasteurization. Using the Electropure Pasteurizer, Supplee and Jensen¹³ worked with times of 15 seconds to as little as .8 second over a temperature range of 62.8°C. (145°F.) to 85°C. (185°F.). High bacteria effectiveness was observed for periods as short as .8 second.

Effect of Ultraviolet Light on Bacteria in Milk. Although ultraviolet light is lethal to microorganisms, when it can reach them directly, it does not destroy all of them in milk. This is because the rays cannot penetrate opaque substances like milk. Besides this milk which has been subjected to irradiation with ultraviolet, has changed flavor and odor. Ayers and Johnson,⁶² Schultz,⁶³ and Houghton and Davis⁶⁴ observed very low percentage reductions of viable microorganisms. Attempts to use ultraviolet rays for this purpose were also unsuccessful in the hands of Gerber and

61. Holmquist. 1931. Internatl. Assoc. Dairy and Milk Insp., 20th Ann. Rpt., 1932, 79-100; see also next paper.

64. Houghton and Davis. 1914. Amer. J. Pub. Health 4, 224-240.

Hirschi.⁶⁵ Mancovitz⁶⁶ found it possible to destroy many bacteria in milk in less than 45 seconds' exposure to ultraviolet ray. Such milk, however, was unmarketable owing to off-flavors. Using an average time of 19 seconds, and average reduction in bacterial counts from 69,000 per ml. in the untreated raw milk to 4,500 per ml. in the treated milk was obtained. The taste and smell of the milk was not affected by the shorter time exposure.

The number of bacteria in low-count milks was not greatly changed in experiments by Wechel⁶⁷; however, there were reductions in high-count milks. These were of little significance since they averaged 28 per cent. It was also found that the keeping quality of irradiated milk was improved even in milk of good quality where there was no appreciable effect of radiation on the bacteria count. By introducing cultures of *Streptococcus lactis*, *Escherichia coli*, or *Bacillus coagulans* into the milk it was found that the radiation as applied to milk had no selective action on the various organisms normally found in milk.

Intensity and spectral characteristics of the radiation employed greatly influence lethal effectiveness of ultraviolet rays (Supplee, Flanigan, and Jensen⁶⁸). Using the "Sterilamp" of the Westinghouse Electric Mfg. Co., they found that greater bactericidal effect was obtained with a smooth-flowing milk film than with films flowing over corrugated cooler surface. Radiation in the 2,200 to 2,300 Å region gave erratic bactericidal results. Sublethal doses might cause stimulation. Percentage reduction in bacterial counts of raw mixed milk in excess of 90 per cent and frequently up to 95 to 98 per cent were obtained with a high degree of regularity by preferred methods of applying ultraviolet radiation of appropriate intensity and spectral characteristics.

Cooling of Pasteurized Milk. Pasteurized milk must be cooled promptly and well, else the bacteria which have survived will grow. If cooling is not adequate the milk may remain too long at a temperature which is incubation for bacteria. The difficulties involved are probably the main reasons why pasteurization in the final package has not been successful. Ayers, Bowen, and Johnson⁶⁹ reported that milk in containers not larger than quart bottles could be cooled by forcing cold air downward over them when the temperature of the air was 4.4°C. (40°F.) or lower. Brew⁷⁰ studied the subject of cooling under various conditions. He did not find air cooling efficient at temperatures above the freezing point.

In former years, it was suggested that cold shock after heating would destroy many bacteria which had survived any heat treatment. This has found little support in experiments of various kinds. Ayers and Johnson⁷¹ promptly cooled milk which had been pasteurized in the laboratory at 62.8°C. (145°F.) and 71.1°C. (160°F.) for one-half hour. No evidence could be secured that prompt cooling had any effect on bacterial numbers.

BACTERIA IN PASTEURIZED MILK

Bacteriologists once believed that sporeforming bacteria mainly survived pasteurization in milk. This idea resulted from observations on heating pure cultures of bacteria in other menstrua where most of them were destroyed. A different situation was later found to obtain for milk. Some of the earlier information resulted from experiments in which the milk was boiled. Under such conditions, sporeforming bacteria would probably be about the only types which would survive. When lower temperatures were used, nonsporeforming species were found. The literature on this subject has become voluminous. Ayers and Johnson⁶² by means of their so-called "milk-tube" method were able to secure information which helped to correct some of the erroneous opinions which had been held previously. Owing to survival and development of nonsporeforming, lactic acid-producing bacteria, milk pasteurized at temperatures generally considered to be acceptable for destruction of pathogenic bacteria, soured in the normal manner. They found that the relative proportion of the groups of peptonizing, lactic acid-producing, alkali-forming, and inert bacteria in pasteurized milk was about the same as in raw milk. Ayers and Johnson, as did Weigmann⁷² *et al.*, observed lactic acid-producing bacteria with sufficiently high thermal death times to survive ordinary pasteurization procedures. Russell and Hastings⁷³ reported a micrococcus from milk which withstood 76°C. (168.8°F.) for 10 minutes. When studying the ability of streptococci to survive pasteurization, Ayers and Johnson^{62,71} stated that the "absolute" and "majority" thermal death points of the bacteria should be taken into account. They called attention to the fact that only relatively small amounts of the total volume of the pasteurized milk can be examined, and that this factor in technic is, therefore, very important when results are interpreted. The "majority" thermal death point is different from the "absolute" thermal death point. Prucha⁷⁴ attacked this problem in two different ways: first, the effect of pasteurization on the entire bacterial flora in milk; second, the different bacterial species found in milk were obtained in pure cultures and then subjected to the pasteurizing temperature. The results obtained corresponded, in general, with the results of previous investigators. Pasteurization reduced the bacterial count in the milk in general about 99 per cent. However, under certain conditions, the milk became heavily contaminated with bacteria that were resistant to the pasteurizing temperature. When that happened, pasteurized milk had high bacterial counts. The flora usually consisted of varying numbers of different species, each species varying in numbers from day to day. According to Prucha, various methods employed in connection with milk production and handling affect the number of bacteria and the percentages of different species. Not only the methods of operation, but also the weather and the climatic temperatures will affect the bacterial flora of milk. The source of these bacteria was not fully demonstrated in all cases. There was some evidence that they came from utensils. Incom-

plete steaming of utensils permitted some organisms to survive, while those that are more sensitive to heat were completely destroyed. Heat-resisting bacteria did not grow very fast in milk when the milk was kept at lower temperatures. They did not seriously affect the keeping quality of the milk when the milk was kept at 15.6°C.(60°F.) or lower. However, the high counts in freshly pasteurized milk, whether the counts are due to thermophiles or to the heat-resisting bacteria or to the spore-producing bacteria, should always be considered to indicate neglect somewhere along the journey of the milk as it passes from the cow to the final container, the bottle. A later report was made by Brannon and Prucha.⁷⁵ Sterile milk was inoculated with the pure cultures and the milk was heated at temperatures between 55.5°C.(132°F.) and 62.2°C.(144°F.). Thirty of the organisms studied were greatly reduced in numbers as low as 55.5°C.(132°F.) with four or five exceptions. All nonsporeforming bacteria were destroyed at 61.1°C.(142°F.), but no sporeforming organism was completely destroyed at 62.2°C.(144°F.).

Results of experiments by Thurston and Olson⁷⁶ also showed that lactic acid-producing bacteria survived pasteurization of low-count milk during storage. Coagulation occurred at low acidities, probably owing to the production of a rennin-like enzyme by the bacteria. There was no tendency for peptonizing bacteria to overgrow other types in raw or pasteurized bottled milk held for four days at 2.2 to 13.3°C.(36 to 56°F.). The pasteurized bottled milk tended to develop a "cappy" flavor after two days' storage at the above temperatures. Prouty's⁷⁷ work on pasteurizing low-count milk confirmed again present-day knowledge on this subject. Based on a study of 75 corresponding samples, each of raw and commercially pasteurized milk, pasteurization at 61.6 to 62.8°C.(143 to 145°F.) for 30 minutes resulted in a decrease in the percentage of acid-forming bacteria from 29.4 to 18.8, a decrease in the percentage of the proteolytic group from 7.0 to 5.0, and an increase from 63.6 to 76.2 per cent in the alkali-forming and inert group. After 24 hours' incubation at 21.1°C.(70°F.) the group percentage in raw and pasteurized milks, respectively, were as follows: acid-forming, 92.1 and 12.4; alkali-forming and inert, 7.35 and 86.4. No significant differences existed in the proportion of the proteolytic group in the two kinds of milk. After 48 hours' incubation at 70°F. the group percentages in raw and pasteurized milks were as follows: acid-forming, 96.0 and 76.1; alkali-forming and inert, 3.96 and 23.7 per cent, respectively. The proteolytic group constituted less than one per cent of the flora of either type of milk. Twenty per cent of the pasteurized samples developed a pronounced bitter flavor without accumulation of more than .4 per cent acid.

Heat resistance of bacteria and the factors which influence it have been discussed in several other places in this book. In general, the same principles may be said to be involved in destruction of bacteria in milk by pasteurization that are involved when other foods are heated for destruc-

tion of bacteria. The process is not a simple one but subject to many conditions. Among these the vigor and condition of the bacterial cells, themselves, have not received sufficient attention. In experiments by Sherman and Stark⁷⁸ age of bacterial cells influenced greatly their susceptibility to heat, young cells succumbing easily. Milks held at temperature at which bacterial growth takes place (e.g., 15.5°C.) show a greater percentage destruction of bacteria than occurs in similar milks when fresh or when held at a temperature (e.g., 4.4°C.) too low to allow multiplication of the bacteria involved. Some important milk bacteria (e.g., "ropy milk" types) may be entirely eliminated from milk by pasteurization when the cells are in a young and growing condition, while the old cells of the same organisms can withstand the process. Anderson and Meanwell⁷⁹ observed fluctuations in heat resistance of two streptococci strains at pasteurization temperatures, the most important being an increased resistance as the temperature for growth was lowered below the optimum. At these temperatures, one showed a progressive increase in resistance during the early logarithmic growth phase. Similar changes were shown by a second streptococcus isolated from pasteurized milk. Both cultures showed increased resistance as a result of 24 hours' cold storage. This was most marked when the low temperature was applied during the early logarithmic phase of growth. Both strains were *Streptococcus thermophilus* types; it is not known whether other strains behave in the same manner. The practical application is in relation to the usual practice of low-temperature storage of milk before pasteurization and its possible influence on increasing the heat resistance of the streptococci so held. Another factor to which less attention has been given is the influence of hydrogen-ion concentration of the milk. Mattick and Nichols⁸⁰ stated that the number of bacteria surviving decreases as the hydrogen-ion concentration decreases. This observation is in keeping with results secured when heat is applied to other acid foods.

The bacteria which may survive pasteurization are varied and may be arranged into the following groups:

1. Heat-resistant, nonsporeforming bacteria. These are said to be of two classes (Ayers⁸¹): first, those which have a low majority thermal death point in which only a few cells survive; and second, those which have a high majority thermal death point. Proper pasteurization at 62.8°C. (145°F.) for 30 minutes allows only a few of the first class to survive in large numbers but those of the second class may be present in large numbers. If there are large numbers of heat-resistant bacteria in the raw milk they will survive to appear in the pasteurized milk. These organisms can be of no great significance since they are nonpathogenic. Hucker,⁸² when studying 180 strains of cocci which resisted pasteurization, found that *Streptococcus thermophilus* Orla-Jensen was the predominating coccus in freshly pasteurized milk. Various Micrococci encountered in pasteurized milk were believed to indicate use of dirty utensils by Hileman, Leber, and Speck.⁸³ Some of these organisms may be of interest in view of their ability to form products which are toxic by mouth. Breed (chairman)⁸⁴ reported variable re-

sistances to heating in milk at 62.8°C.(145°F.) for 30 minutes. These organisms are frequently found on plates made from pasteurized milk. Investigation revealed that some micrococci of sanitary significance might survive pasteurization in milk at 62.8°C.(145°F.) for 30 minutes. Survival of streptococci is an interesting problem because of its possible significance. Some streptococci have been connected with pathologic conditions, while other species are considered to be very desirable. Ayers, Johnson, and Davis⁸⁵ reported that certain streptococci from pathologic sources survived heating in milk at 60°C.(140°F.) for 30 minutes.

Peiser⁸⁶ found in milk and cream pasteurized at 63°C.(145.4°F.) a number of strains of the *Bacterium lactis acidi* type, whose thermal death point in broth was below pasteurization temperature. The average thermal death point is in whole milk 5°C., in separated milk 2.5°C., and in whey .5°C., higher than in bouillon. These results indicate that the protection given to the suspended lactic bacteria by the casein and coagulated albumin of separated milk raises their thermal death point 5°C. These results have been confirmed by Ayers and Johnson⁸⁷ who studied the subject with a great number of *Streptococci*. The thermal death points of 139 cultures of streptococci isolated from cow feces, from the udder and the mouth of the cow, and from milk and cream showed a wide variation when the heating was performed in milk for 30 minutes under conditions similar to pasteurization. At 60°C.(140°F.), the lowest pasteurizing temperature, 89 cultures, or 64.03 per cent, survived; at 62.8°C.(145°F.), the usual temperature for pasteurizing, 46, or 33.07 per cent survived; and at 71.1°C.(160°F.), 2.58 per cent of the cultures survived; all were destroyed at 73.9°C.(165°F.).

The streptococci from the udder were, on the whole, less resistant and those from milk and cream more resistant to heat in general. This was confirmed by a very extensive investigation reported by Ayers and Johnson.⁸⁸ Streptococci isolated from milk, cow feeds, mouth of the cow, etc., showed wide differences in heat resistance when studied in milk. Ayers and Johnson stated that two classes of streptococci seemed to survive pasteurization: (a) Streptococci which have a low majority thermal death point, but among which a few cells are able to survive the pasteurizing temperature. This ability of a few bacteria to withstand the pasteurizing temperature may be due to certain resistant characteristics peculiar to a few cells, or may be due to some protective influence in the milk. (b) Streptococci which have a high majority thermal death point. When such is the case, the bacteria survive because the majority thermal death point is above the temperature used in pasteurization. This ability to resist destruction by heating is a permanent characteristic of certain strains of streptococci. Ayers and Johnson made their studies in milk under conditions which probably reflect those in actual pasteurization by the holder process.

Microscopic examination of bottled pasteurized milk by Way⁸⁹ showed large numbers of streptococci occurring usually in pairs and sometimes in chains of four or six. In raw milk the chains were longer. Agar plate preparations showed predominance of small "pin-point" colonies. After heating a specimen of milk containing 80,000 of these cells, their concentration was practically unchanged. They withstood 72.5°C.(162°F.) for one hour. These organisms were traced to cow feces and Way believed that large numbers of them indicated insanitary conditions.

Thermoduric Bacteria. These are heat-resistant bacteria which are not thermophilic. They survive pasteurization temperatures but do not develop at them. They are known to exist in the udder and also reach milk from utensils which harbor them. Hileman⁹⁰ prepared a review of the literature dealing with these forms. Maack⁹¹ believed that they came from

utensils and apparatus which had not been thoroughly cleaned. Prucha and Maack⁹² found many of these bacteria to be Gram-positive, coccus forms coming mainly from utensils. A new thermoduric bacterium, *Sarcina thermodurica* was reported by Wainess and Parfitt.⁹³ This organism resisted pasteurization and was isolated from milking machines and other utensils. Introduction of tryptone glucose skim-milk agar as the standard plating medium changed the picture for thermoduric bacteria, as pointed out by Hileman, Moss, and Stead.⁹⁴ They believed that a higher percentage of bacteria in raw milk are now appearing as thermoduric forms. Season and quality of raw milk contribute to variations in the number of thermoduric bacteria. Macy and Ereksen⁹⁵ stated that thermo-tolerant organisms may be found in low-count as well as in high-count milk, but a higher proportion of the poorer quality milk will be difficult to pasteurize satisfactorily regardless of the season. Fewer bacteria survived laboratory pasteurization in winter than in summer, which Macy and Ereksen believed was due to more thermoduric bacteria in summer milk. Both utensils and faulty cooling were said to be the cause. Careful washing of utensils was one method of meeting the problem of thermoduric bacteria.

Mallman, Bryan, and Fox's Procedure for Detecting Source of Thermoduric Bacteria in Milk. High counts of bacteria in pasteurized milk are often due to thermoduric bacteria and not improper pasteurization. While these bacteria are of no public-health significance, they do indicate unclean equipment and unclean practice in the dairy. After much study of the problem, Mallmann, Bryan, and Fox⁹⁶ suggested a standard of 40,000 bacteria per milliliter in milk incubated at 56 to 60°C. (132.8 to 140°F.) for two hours as the limit for objectionable numbers of thermoduric bacteria. The procedure was as follows:

1. Place five-ml. to 10-ml. samples of milk suspected of containing thermoduric bacteria in an incubator at a temperature of 58-60°C. (136.4-140°F.) and incubate for two hours.

2. By means of the microscope, with the usual procedure, count the bacteria which are present.

3. Samples showing more than 40,000 bacteria per milliliter contain thermoduric bacteria in excessive numbers.

Graham and Orme's⁹⁷ Procedure for Detecting Thermoduric Bacteria in Milk. This procedure consists of two steps, the first to check the efficiency of pasteurization in the plant being inspected and the second to detect the offending shipper. In the investigation of an outbreak, samples should be taken from all vats in the plant at the conclusion of the holding process and before cooling. Each sample is cooled in the sample bottle and taken to the laboratory. Here, the sample is divided and a portion repasteurized and original samples are then replated. Several dilutions should be used and incubation should be at 37°C. (98.6°F.). If thermoduric organisms are present there will be little or no reduction in the count on the plates from the repasteurized sample. In such cases individual samples are taken from each producer's milk and part of each of these subjected to laboratory pasteurization. Plates are then prepared using a dilution of 1:1000 for the raw milk and 1:100 for the pasteurized. The presence of thermoduric organisms will be indicated by a high count on the plates from the pasteurized

samples. In such cases, further work will have to be done on the farm. Improperly cared for milking machines are often the cause of the trouble.

Marcus'⁹⁸ Method for Determination of the Number of Thermoduric Bacteria in Milk. Control of thermoduric bacteria in milk in the Boston area is accomplished with results of laboratory pasteurization experiments. Marcus stated that 10-ml. samples of milk are collected in 18-ml. aluminum screw-cap vials and placed in a water bath at 61.9°C.(143.5°F.) for 30 minutes. Addition of the cold-milk samples causes the temperature to drop. The holding period is computed from the time the temperature returns to 143.5°F. Counts are made with the standard plating medium with incubation at 32°C.(89.6°F.).

Myers and Pence^{98a} Method for Laboratory Examination of Raw Milk Supplies for Thermoduric Bacteria. The technic of examination of raw milk for thermoduric bacteria was stated as follows: After a 5 ml. sample of milk in a screw-capped test tube has been pasteurized in the laboratory at 61°C.(143°F.) for 30 minutes, it is vigorously shaken. With a standard loop, giving .001 ml. of milk (occasionally one giving .01 ml.) a loopful of the milk sample is transferred to the oval culture tube containing about 4 ml. of melted tryptone-glucose-extract agar, which has been previously sterilized and cooled to 45°C. The loop is moved back and forth through the agar to remove all of the milk from the loop. The agar medium and milk are then mixed by swinging the tube through a long arc. The tube is then laid on the table with the open end resting on a strip of wood or metal one-eighth inch thick, to cause the medium to flow to a point 2½ to 3 inches from the bottom on the tube. When the agar is solidified, the tubes are incubated at from 36° to 37°C. for 48 hours. The colonies are counted in the usual manner. Fischer and Johns^{98b} found this procedure to be more satisfactory than others proposed for the same purpose.

2. Thermophilic bacteria which grow well at pasteurization temperatures. These bacteria have caused some interesting problems in dairy bacteriology. Some of them grow only at temperatures around 55°C.(131°F.) while others develop at lower temperatures also. The former would not develop on the standard agar plates incubated at 37°C.(98.6°F.) while some of the latter might. Introduction of a lower temperature of incubation, 32°C.(89.6°F.) will complicate the situation, particularly in respect to comparison of results with the new medium and those with the old one.

A standard plate count, as ordinarily determined, especially of pasteurized milk, probably does not reveal the presence of thermophilic and thermoduric bacteria. These organisms may be present in pasteurized milk in large numbers and yet not be revealed by the plate count. They are significant because they may attack some of the milk consistently, either fermenting lactose or decomposing proteins and producing off-flavors and bad odors. In view of this fact, many boards of health have not concerned themselves with these organisms. They have taken the attitude that since they do not develop under ordinary conditions their presence may be ignored. This is a questionable position because thermophilic bacteria are just as much a part of the bacterial population of milk as any other flora. Furthermore, the thermophilic bacteria may be a good index of undesirable conditions in the production of the milk. Another reason why they have been practically ignored is because they are nonpathogenic. The Connecticut State Board of Health, in its Annual Report for the year 1937, page 195, gives the results of a short survey to determine the presence of these organisms in market milk. Direct microscope counts by the Breed method and the standard agar plate were made on samples of pasteurized milk for about a year. For this purpose only large rods and sporeformers were counted, although it is known that other types of thermophilic and thermoduric organisms exist. Nearly 20 per cent of all samples examined contained these organisms. The bureau which did this work contended that detection of thermophilic bacteria in pasteurized milk by cultural and microscope methods was desirable and that such counts would contribute information obtainable in no other way as concerning plant practice.

98. Marcus. 1942. N. Y. Assoc. Dairy and Milk Insp., 15th Ann Rpt.

98a. Myers and Pence. 1941. J. Milk Tech. 4, 18-25.

98b. Fischer and Johns. 1942. Idem. 5, 269-275.

Rogers and Frazier⁹⁹ believed a high number of thermophilic bacteria in milk indicated one or more of the following: the pasteurizing plant may be receiving unusual contamination; it may be repasteurizing milk brought back from the wagons; the walls of the pasteurizer may have a thin layer of cooked milk in which thermophiles grow; the construction of the pasteurizer may be defective so that some of the milk fails to reach the pasteurizing temperature; there may be an excessive amount of foam which is not heated to temperature; or the vats may not be cleaned between runs. Ward, Adams, and McCutcheon¹⁰⁰ observed thermophilic bacteria predominating in nearly 50 per cent of the samples of pasteurized milk which they examined. In other samples they were present in lesser numbers. Thermophilic bacteria are probably the cause of one type of "pin-point" colony. Wright¹⁰¹ claimed that these are largely *Streptococcus thermophilus* and are thermoduric. Ordinary standard media containing milk or lactose should be employed.

In view of the fact that the standard agar plate is not sufficient to show the real bacterial condition of pasteurized milk in routine milk-control work, Breed¹⁰² recommended that his direct microscope method be used simultaneously with the agar plate. When large rod-shaped bacteria were revealed by the microscope, the probable presence of thermophilic bacteria was indicated.

Bacteria in pasteurized milk that stained well in methylene blue were usually found to be alive. The failure of obligate thermophiles to grow on plates as ordinarily incubated limits the usefulness but does not discredit the use of the standard agar plate in the official control of pasteurized milk. Some might wish to take issue with this statement. Introduction of high temperature-short time methods of pasteurization prompted inquiry about the behavior of thermophilic bacteria under these new conditions. This problem was studied by Yale and Kelly¹⁰³ in four plants using the Electropure process, two the Isotherm, two the precision, and one the York plate-type pasteurizer. The details of bacteriological technic need not be given here. It was found that the following plant practices were responsible for growth of thermophilic bacteria in the pasteurizing equipment: repasteurization, prolonged holding of hot milk in equipment as result of a shut-down, passage of hot milk through the same filter cloth for three hours or more, cooking of milk solids on to the walls of the regenerative heater and faulty sterilization of equipment.

The Milk Ordinance and Code of the United States Public Health Service¹ states as follows: "*Thermophiles*—If the pasteurization plant becomes infected with thermophilic organisms, it may prove that more intensive bactericidal treatment or a change in methods may be necessary. If the steam or hot water method has been in use, an attempt should be made to use higher temperatures and for longer periods (above 200° for more than 10 minutes)."

The methylene-blue reduction test has been applied to detection of thermophilic bacteria in pasteurized milk. Harding and Ward¹⁰⁴ observed a shortening of the reduction time by pasteurization and attributed this to the activity of thermophilic bacteria. Thomas¹⁰⁵ also found the methylene blue reduction test a sensitive test for detecting presence of thermophilic bacteria in milk. Thermophiles were detected in most samples of raw milk produced under unsanitary conditions but in only three per cent of the clean raw samples. These organisms were isolated from hay, straw, silage, bran, and cow manure. A brief description of the morphology and cultural characteristics of some thermophiles isolated from milk is presented. Meanwell¹⁰⁶ believed that decolorization in 30 minutes was a sign of trouble.

3. Non-thermophilic sporeforming bacteria. These organisms on account of the presence of spores resist pasteurization and appear in the heated milk. Such organisms were studied by Robertson, Yale, and Breed.¹⁰⁷ They observed occasionally large numbers of sporeforming rods by the microscope (Breed) method, which did not grow on plates in the same abundance as they appeared in the films for microscope examination. The source of these rods was found to be milk cooked onto the pasteurizers in which these organisms grew during the periods when the pasteurizer was empty. Cultures isolated from material scraped from the sides of the pasteurizers proved to be identical with the sporeformers isolated from the pasteurized milk. Of 140 cultures, 48 proved to be *Bacillus subtilis* Cohn, 29 were *Bacillus mesentericus* Trevisan, 22 *Bacillus vulgatus* Trevisan, 21 *Bacillus circulans*, Jordan, 10 *Bacillus albolactis* Migula, 2 *Bacillus laterosporus* Ford, 1 *Bacillus cereus*, Frankel and 1 *Bacillus mycoides*, Flügge, and five were not identified. This work showed that some of the commonest bacteria in nature may be responsible for high counts in pasteurized milk.

Flügge¹⁰⁸ was one of the first to believe that heated milk might contain bacterial spores and that these might later germinate. Three species of peptonizing bacteria were isolated from heated milk which caused the death of experimental animals. Since Flügge's milk was heated to the boiling point and not at temperatures ordinarily used for pasteurization, his conclusions ought not to be applied to modern pasteurization. Colwell and Sherman¹⁰⁹ reported that pasteurization at 60°C.(140°F.) seemed to restrain the peptonizing bacteria as much as the acid-forming bacteria. Ford and Pryor¹¹⁰ attempted to confirm the earlier findings of Flügge to the effect that milk always contains heat-resistant spores of aerobic and anaerobic bacteria, which, by their development, can give rise to disagreeable and unwholesome changes in milk, converting it from a food of great nutritive value into an undesirable if not a dangerous article of diet. The results seemed to justify the warning that any milk heated to temperatures below the boiling point, might undergo undesirable changes if not kept cold.

The bacteria which resist pasteurization and appear in pasteurized milk were also studied by Marshall.¹¹¹ Prucha⁷⁴ pointed out that, under certain conditions, the milk may become contaminated with sporing bacteria, and then high bacterial counts after pasteurization will result. Figures are given of as many as 1,600,000 bacteria left in the pasteurized milk. Such results may occur with cows contaminated with numbers of spore-producing soil bacteria, occasionally with incompletely sterilized utensils, the more resistant strains surviving and multiplying in the moisture left in the vessels. The presence of these heat-resisting bacteria indicates some neglect in milk cleanliness precautions.

Bliss¹¹² found *Clostridium welchii* in 90 per cent of raw and pasteurized samples of milk in Baltimore. An interesting factor in connection with the pasteurization of milk was brought out by Sherman, Stark, and Stark,¹¹³ who stated that the age of the cells had much to do with the results of pasteurization. Young cells were more easily killed than older cells. More data on this question are necessary before the significance of Sherman's conclusions may be fully appreciated.

Growth of Bacteria in Pasteurized Milk. Several investigators have reported that pasteurized milk is much more susceptible to decomposition by

bacteria than is raw milk. Allen¹¹⁴ said that raw milk, as compared with pasteurized milk, exerts a powerful suppressing influence on multiplication of certain bacteria. Pasteurized milk was found to be more favorable to the attack of *Escherichia coli* and *Aerobacter aerogenes*. Allen emphasized the point that pasteurized milk, although it is safe for human consumption, should be handled with much care, since heating has decreased its resistance to many detrimental changes. Ayers and Johnson,¹⁷ reported that the bacterial increase in clean raw milk and pasteurized milk was about the same when both were stored under the same conditions. Ford and Pryor¹¹⁰ also expressed this opinion as did Cripps and Purvis.¹¹⁵ Ayers and Johnson believed it to be manifestly unfair to conclude that bacteria increase faster in pasteurized than in raw milk, simply from a comparison of the ratios of bacterial increase. If pasteurized milk with a low initial count is compared with a raw milk of high bacterial content, then the ratios of increase may show that the bacteria in the heated milk do increase faster; on the other hand, if the same pasteurized milk is compared with a clean raw milk with a low count, then the ratios of increase will be found to be approximately the same. From the results of Ayers and Johnson's investigation, it is evident that bacterial increase in an efficiently pasteurized and a clean raw milk is about the same when the samples of milk are held under similar temperature conditions. This question of the relative growth of bacteria in raw and pasteurized milk can be properly settled only by a long series of comparisons of samples of milk with approximately the same bacterial count and similar bacterial group percentages. Andresen¹¹⁶ has reported the existence in raw milk of a thermolabile agent which inhibits the paratyphoid organism.

Control of Pasteurization and Milk Pasteurizers. Since pasteurization was introduced to make milk safe and since it is one of the most important steps in processing fluid milk, it is subjected to official regulation and control. The reasons for this are obvious. Consumers must be assured that they are using properly pasteurized milk, else they use it with a false sense of security. Efforts to control and to supervise this process include inspection of and improvements in pasteurization apparatus, and application of tests to the heated milk to determine whether it has been satisfactorily treated. The former part of the problem has been considered at some length by the committees of the American Public Health Association. Necessity of changing certain features in the construction of pasteurizers was soon realized. These had to do largely with prevention of dead-ends or pockets in which some of the milk might not be heated to the pasteurization temperature and to inspection regularly of the thermometers. Necessity of frequently checking temperature recording devices used on pasteurization machinery has been pointed out by Tiedeman and Swanner.¹¹⁷ When the New York State Department of Health began checking thermometers some of them were found to read 9.4°C. (15°F.) too high. This is more dan-

gerous than to have too high temperatures. Zeller ¹¹⁸ believed that the best guarantee of efficient pasteurization was careful supervision at the dairy and careful temperature control. He placed less confidence in tests applied to the heated milk because none had been developed at that time which could be relied upon. Of the enzyme reactions then available, he believed the Schardinger aldehyde-catalase test to be most satisfactory. Moore ¹¹⁹ found that the main difficulty in pasteurization practices rested on the failure to heat the milk to the necessary temperature or to holding it at the stated temperature for the required length of time. Similar conditions were found in New Jersey. In 85 per cent of the cases, the milk was not being held the full length of time. Such situations have been largely corrected by reconstruction of apparatus, the phosphatase test, and education of those who operate pasteurizers.

Owing to the fact that *Mycobacterium tuberculosis* was found in milk which was being sold as pasteurized, the Ministry of Health of Great Britain ¹²⁰ found it necessary to more strictly control the process. This was done with the help of the phosphatase test. A large portion of the milk supplied schools in Reading, according to Milligan ¹²¹ was inadequately pasteurized. This has been the experience in other places and it indicates the need for regular and constant control.

Some have even advised that operators of pasteurizers be especially trained and made to feel their responsibility to the public. Cohee, Hostetter, Mitchell, Morgan, and Steele,¹²² a committee of the Pennsylvania Association of Dairy and Milk Inspectors, recommended that those who supervise pasteurization in Pennsylvania be required to demonstrate their ability by passing an examination set by Pennsylvania State College. This has been proposed on several different occasions by Savage ¹²³ in England. According to this authority granting of licenses to sell pasteurized milk rests with local authorities. Official requirements in England are (1) temperature between 62.8°C.(145°F.) and 65.6°C (150°F.) for at least 30 minutes with immediate cooling to not more than 12.8°C. (55°F.); (2) indicating and recording thermometers to be used and type of apparatus and thermometers and methods employed to be satisfactory to licensing authority; (3) temperature records kept for at least a month; (4) milk after pasteurization and before delivery shall not have more than 100,000 bacteria per milliliter. For laboratory control, two tests in addition to the plate count are recommended: (1) the coliform test—three 10-ml. tubes after milk is bottled, maximum allowable, one tube positive; (2) the phosphatase test—maximum allowable, 2.3 units Lovibond blue.

Bacteriological Methods of Control. It would be logical that these would be used first. Difficulties in examining milk for *Mycobacterium tuberculosis* caused bacteriologists to attempt to use colony counts as an index. This

method resolved into "percentage reduction" in numbers of bacteria before and after pasteurization. This method has been largely abandoned for better ones. "Percentage reductions" may not always mean what they seem to. Hussong and Hammer¹²⁴ observed large variations in percentages of bacteria killed in samples of raw milk from different farms as well as in samples from the same farm. They believed that a close relationship of initial counts on raw milk to counts on pasteurized milk did not exist. In some cases the count on pasteurized milk exceeded the count of raw milk, indicating the presence of a heat-resistant flora. Unreliability of plate counts was also stressed by Tiedeman and Hohl.¹²⁵ They believed in the results of the phosphatase test.

Some bacteriologists have advised testing pasteurized milk for presence of coliform bacteria. Such recommendations rest on the belief that these bacteria are destroyed in milk at temperatures used for pasteurization, a question which is discussed at some length later in this chapter. Savage¹²⁶ believed that this method had merits.

The Ministry of Health of Great Britain has adopted the following requirements for control of pasteurization.

"On a sample of milk being taken at any time after pasteurization and before delivery to the consumer, the milk shall be found not to contain (a) more than 30,000 bacteria per cc., nor (b) any *Bacillus coli* in one-tenth of a cc."

After mentioning several that may be used, Leete¹²⁷ described a method that had been developed by the United States Department of Agriculture for testing the efficiency of pasteurization. For this purpose he proposed *Serratia marcescens* (*Bacillus prodigiosus*) as the efficiency indicator since it is nonpathogenic, easily isolated, easily killed, and is not widespread in natural waters. The exact technique was described as follows:

Leete's Method for Determining Efficiency of Pasteurizers. Twenty-four-hour old cultures of *Serratia marcescens* (*Bacillus prodigiosus*) are washed off in approximately 100 ml. of sterile water. Three slants are sufficient for a 4,000 to 6,000 pound machine. The water with the washed cultures is then shaken and filtered through filter paper. The method of making the test in detail under field conditions is as follows: Use of a pasteurizing plant is secured and the test is made either before or immediately after the regular run of milk. The holders, together with the necessary pumps, heaters, etc., are cleaned in the usual manner. The outfit is completely filled with ordinary tap water. Also, the supply tanks are filled with sufficient water to run the apparatus at its rated capacity for 30 minutes. A sufficient water supply is imperative. After the outfit has been filled, the pumps are started, or in the case of gravity-filled tanks the valves are opened. In this test it must be remembered that the water is run through at ordinary temperatures, rather than at pasteurization temperature. Constant checks upon the quantity of water passing through the machines are made at the outlet, in order to regulate the flow. This is done by actual measurement and timing. These checks are made at frequent intervals during the run. The rate of flow should always be constant and should correspond to the rated capacity of the holder. Samples of water for bacteriological analysis are taken at the supply tanks, at the inlet of the holder, or as near this point

as possible, and at the outlet. These samples serve as bacteriological checks upon the water and apparatus.

The test organism is then introduced at the inlet to the holder and the time noted. In some types of machines it is impossible to introduce the culture immediately into the holder. The culture is then placed at the entrance to the heater. This should in no wise detract from the accuracy of the test, for the time taken in passing through the heater is relatively short, and a portion of this time may be considered a part of the holding time, in that the milk while in the heater has reached the proper pasteurizing temperature.

Samples of the effluent are collected at the outlet, the time in each case being noted. These samples are for bacteriological analysis and must be taken aseptically. Sterile test tubes can be used for the collection of samples. The greater the number of samples taken, the more accurate will be the results. For ordinary purposes, samples taken at three-minute intervals for a period of 18 minutes, and then every minute up to 30 minutes will give accurate results. For additional study and information, samples should be taken up to 45 minutes. All samples taken, including the check samples, are then plated. One milliliter of each sample is plated directly on a plain agar medium. The plates are incubated at room temperature for 48 hours. At the expiration of this time a study of the plates is made. The holding time is computed as the elapsed time between introduction of the organism at the inlet and its recovery at the outlet. The identification of the test organism is easily made, microscopically, owing to its very characteristic luxuriant, bright red growth. In all cases, the check samples secured before the organism was introduced must be negative—that is, show no red colonies—if the test is to be relied upon.

Tanner and Windsor¹²⁸ found that the markedly low heat resistance of *Serratia marcescens* (*Bacillus prodigiosus*) might be a serious objection to the use of the organisms in this manner. None of the strains which they used survived nine minutes in milk heated to 62.8°C. (145°F.). Disappearance of the organism might occur in a much shorter holding period than 30 minutes, which is the accepted time in the continuous method. It is not easy, as Ayers¹²⁹ stated, to secure methods for controlling pasteurization. Bacterial counts are not satisfactory alone for they have decided limitations in themselves. It is probably equally difficult to secure an organism which may be used as an indicator of adequate pasteurization. McCrady and Langevin¹³⁰ also found plate counts inadequate for control of pasteurization apparatus. Since organisms of the coli aerogenes group are seldom found in properly pasteurized milk, it was suggested that their presence would indicate improper pasteurization.

After Leete's¹²⁷ method of testing pasteurizing machinery had been published, Goehrig¹³¹ of the New Jersey State Board of Health used it for checking pasteurizers in that state. He reported some very interesting results. Up to the time of Goehrig's publication, 49 pasteurizing plants had been examined, 42 of which used the continuous flow system, while seven used the "vat" system, or the compartment type. He found that 19 of these plants showed a holding period of only three minutes; 12 showed a holding period of six minutes; while only four (two of the continuous flow system and two of the vat system) showed a holding period of 30 minutes. Ninety per cent of the holders tested by this method allowed

131. Goehrig. 1925. Pub. Health News, N. J., 10, 220-226.

the milk to pass through in less than 30 minutes. Steps were immediately taken to remodel pasteurizers which would insure the holding of the milk for the full time, at the temperature required by law in that state (61.1 to 60°C.[142 to 140°F.] for 30 minutes).

The Phosphatase Test for Detection of Inadequately Pasteurized Milk. For some time there has been a need for a test which would reveal inadequately pasteurized milk both with respect to time and temperature. Many procedures have been proposed. Health officers have generally relied on inspection of pasteurization plants and machinery including temperature-time charts. Such procedures yield information only for the time when they were made. No, or little, information is given for between times or for the condition of the final product. Any test that is used must involve search for a normal thermolabile constituent of milk or for some added agent which is susceptible to heat. The phosphatase test seems to fulfill the requirements better than any test proposed heretofore. It is now widely used in America and England. Kay and Graham¹³² have devised such a test which is based on the observation that the enzyme phosphatase is destroyed in milk at times and temperatures generally accepted as satisfactory for pasteurization of milk. Phosphomonoesterase is absorbed according to Kay¹³³ by the secreted milk from mammary tissue. Pasteurization at a temperature of 62.8°C.(145°F.) and 65.6°C.(150°F.) and immediately cooling to 12.5°C.(54.5°F.) is just sufficient to inactivate the phosphatase. Lower temperatures will not do so. A known quantity of milk is allowed to act on an excess of well-buffered disodium-phenyl-phosphate for a given time and the amount of free phenol liberated by the enzyme is determined by the Folin and Ciocalteu's reagent. Delicacy is increased by extending the time.

Delicacy of the test was further shown by Koppejan¹³⁴ who stated that phosphatase disappears from milk on heating to 58°C.(136.4°F.), 59°C.(138.2°F.), 60°C.(140°F.), 61°C.(141.8°F.), and 62°C.(143.6°F.) in accordance with a unimolecular reaction. It was removed completely by heating at 62°C.(143.6°F.) for 20 minutes, at 61°C.(141.8°F.) for 45 minutes, and at 60°C.(140°F.) for 75 minutes. A positive was secured by adding as little as .1 per cent of raw milk to pasteurized milk. Tiedeman¹³⁵ also showed that this small amount of raw milk could be detected.

The Kay and Graham¹³² Phosphatase Test for Inadequately Pasteurized Milk. This is a simple test which indicates whether milk has been "legally" pasteurized. The enzyme *phosphatase* is destroyed under conditions which have been proven to adequately pasteurize milk; it is not completely destroyed if the milk is heated to lower temperature. According to Kay and Neave¹³⁶ the test is quantitative and the amount of undestroyed phosphatase is measured in terms of "blue units."

Two tests were proposed: first, a qualitative determination which distinguishes between heated and unheated milk; and second, a quantitative test in which the amount of phosphatase present may be determined and even minor variations in technic detected.

PROCEDURE

Pipette 10 ml. of buffer substrate into each of four test tubes of 20-25 ml. capacity. To two tubes (controls) add 4.5 ml. of diluted Folin's reagent. To all four tubes add .5 ml. of the milk to be tested. Mix well. Add a few drops of chloroform to the two samples (not to controls), cover to protect from dust, warm to 37-39°C. and keep in a 37°C. incubator for 24 hours.

Remove from the incubator, add 4.5 ml. of diluted Folin's reagent to the samples, mix, let stand three minutes. Filter all four tubes. Transfer five ml. of the filtrate to 13 mm. diameter test tubes, add one ml. of 14 per cent Na_2CO_3 , mix, place in boiling water for five minutes and filter. The color of the filtrate is read in a Lovibond tintometer. Colors greater than 2.3 Lovibond units of blue indicate improper treatment.

REAGENTS

1. Buffer substrate. Dissolve 1.09 grams of disodium phenyl phosphate and 11.54 grams of "sodium veronal" in water saturated with chloroform and make up to one liter. Add a few drops of chloroform and keep in refrigerator.

2. Folin and Ciocalteu's phenol reagent. Dissolve 100 grams of sodium tungstate $\text{Na}_2\text{WO}_4 \cdot 2\text{H}_2\text{O}$ and 25 grams of sodium molybdate, $\text{Na}_2\text{MoO}_4 \cdot 2\text{H}_2\text{O}$ in 700 ml. water in a 1,500 ml. flask connected by a ground glass joint to a reflux condenser. Add 50 ml. sirupy (85 per cent) phosphoric acid and 100 ml. of concentrated hydrochloric acid. Reflux gently for 10 hours. Cool, add 150 grams c.p. lithium sulfate, 50 ml. water and a few (4-6) drops of liquid bromine. Boil without condenser for 15 minutes to boil off excess bromine. Cool, dilute to one liter, filter.

The finished reagent should have a golden yellow color with no greenish tint. Any reagent with a greenish tint should be rejected. Keep well protected from dust. Dilute one volume of this stock solution with two volumes of water before use.

3. A 14 per cent solution of anhydrous sodium carbonate, Na_2CO_3 c.p. (14 grams per 100 ml.).

The test is based on the fact that the enzyme hydrolyzes an added phenyl-phosphoric ester liberating phenol, which is readily detected by Folin's reagent. The blue color produced by small quantities of phenol readily lends itself to comparison with permanent standards prepared from inorganic solutions. The test has been approved by various investigators and is one of the important advances in dairy bacteriology. Gilcreas and Davis¹³⁷ after studying it with about 100 samples of milk representing varying conditions of temperature and holding time, believed that it should be a great aid in control of pasteurization. They stated (1936) that variations of five minutes or more in heating time were readily distinguished and addition of as small quantity as one-tenth of a per cent of raw milk gave a result indicative of incomplete pasteurization. Variations in temperature were also easily detected. The technic proved equally satisfactory in determining pasteurization by the ordinary process as by the high-temperature process. A correct evaluation of the character of the treatment to which milk has been subjected was made in 97 per cent of the specimens. According to Fasken and McClure¹³⁸ slight modifications are needed to make Kay and Graham's test suitable for examination of milk pasteurized at 61.7°C. (143°F.) for 30 minutes. The modifications are (1) four-hour incubation, with a limit of 1.8 blue units in place of 2.3, or (2) 24-hour incubation, with a limit of 5.0 blue units in place of 2.3.

137. Gilcreas and Davis. 1937. Internatl. Assoc. Milk Sanitarians, 25th Ann. Rpt., 15-39.

138. Fasken and McClure. 1940. Canad. J. Comp. Med. 4, 128-137.

The Scharer test was found slightly more sensitive than that of Kay and Graham.

Kay ¹³⁹ pointed out that the method loses a certain amount of its precision if it is applied to milk which has been held at a lower temperature than 62.8°C.(145°F.). At the low temperature of 60°C.(140°F.), which is permitted in some parts of Canada, it is less precise and less capable of detecting small errors. Since, however, most of the enzyme is destroyed in 30 minutes at 60°C.(140°F.) it is still capable of yielding valuable results with some modifications. At 61.7°C.(143°F.) it is of material value but there is some loss of its extreme sensitiveness. The phosphatase test is also applicable to control of the high temperature-short time pasteurization process.

Gilcreas and Davis ¹⁴⁰ found no significant variation in phenol concentration resulting when samples were incubated between 24 and 18 hours. but progressive inaccuracies were observed at shorter periods. Artificial color standards maintained an unchanged value for eight months. Reagents and buffer substrate tablets prepared commercially were found satisfactory. The phenol value obtained in the control test has, in general, been found to be negligible, but if abnormally high it should be subtracted from the value obtained in the test in order to determine the phenol concentration corresponding to the degree of treatment of the milk. Unrefrigerated storage of samples for limited periods did not seriously affect the precision of the method. The technic has been applied to the examination of 780 samples collected from delivery trucks and labeled pasteurized. Adequate heat treatment was proven in 96 per cent of the samples, and this precision confirmed previous experience regarding the sensitivity of the test in determining minor, as well as significant, variations in procedures of pasteurization.

While Gilcreas ¹⁴¹ pointed out the great value of the phosphatase test he drew attention to certain difficulties which may obtain. If there is prolonged preheating or slight overheating, the phosphatase content of the milk may be reduced so that the laboratory test may fail to detect five minutes shortening of the holding time or even the addition of one-tenth of a per cent of raw milk. Slightly altered phenol values have to be adopted. If cream is separated from raw milk and then pasteurized, the phosphatase test adequately measures the reliability of the heat treatment. If, however, the cream is separated from pasteurized milk, either by gravity or mechanically, it tends to have an undue high phenol value with the phosphatase test although the initial pasteurization may have been adequate. Many figures are given to illustrate this point. While a full explanation is not available, examinations show a marked concentration of the enzyme in the cream fraction and there may not be complete inactivation at 61.7°C. (143°F.) for 30 minutes. It may become necessary to establish a separate code of readings for cream.

141. Gilcreas. 1939. *Amer. J. Pub. Health* 29, 158-162.

Several incubation periods of the milk plus substrate buffer solution were tested by Storrs and Burgwald.¹⁴² They recommended a five-hour incubation period in testing milk supposedly pasteurized at 61.1°C.(142°F.) for 30 minutes, and a 24-hour incubation period be used where the legal limits of pasteurization are 61.7°C.(143°F.) for 30 minutes. The test was found to be applicable to milk pasteurized by the high temperature-short time method. In this case a 2.5-hour period of incubation was found to be proper for milk pasteurized at 71.1°C.(160°F.) for 10 seconds. When milk is required to be held 15 seconds at 160°F. the 2.5-hour incubation period is too short, and a 24-hour incubation period is too long. A 24-hour period was suitable, however, for milk held for 20 seconds at 160°F. There was no relation between butterfat content in mixed herd milk and the phosphatase content of raw milk and the blue color developed in the pasteurized milk.

The value of results secured with this procedure in actual pasteurization control was shown by Leahy¹⁴³ during a survey of 104 pasteurizing plants in the city of Rochester, New York; a total of 1,563 samples of milk, taken at different stages of the process, were collected from 157 vats, and 2,816 samples of milk from distributors. All samples were examined for improper pasteurization by a modified phosphatase test and for the presence of coliform bacteria employing formate-ricinoleate medium. In the course of a year's study, 50 plants were observed which gave no evidence of improper pasteurization. On the day of inspection, gross defects in pasteurization methods were disclosed in nine plants, routine samples from which were positive. The pasteurization in 24 plants was satisfactory on the day of inspection. Routine samples from these plants, however, were positive and there was evidence of faulty plant operation. With the exception of occasional minor imperfections, the pasteurization in 21 other plants was reliable, and routine phosphatase tests were rarely positive. Leahy found the phosphatase test to be invaluable for detection of improper operation in pasteurizing plants. He emphasized, also, that the test for coliform bacteria is equally valuable for the detection of recontamination by contact with unsterilized equipment at the plant. When both tests are employed simultaneously, they are of more value to the milk industry and public-health officials than any other combination of tests yet devised for milk control. Leahy suggested that the conventional bacterial count be discarded in their favor.

Results of similar investigations by Howell¹⁴⁴ all tend to confirm the value of the phosphatase test as an indicator of efficient pasteurization. Among a series of 216 samples of milk examined in the metropolitan borough of Hammersmith three failed to pass the test. It was discovered that in one case the sample had been taken by dipping a jug into the churn, the jug having just before been used for mixing and dividing a bottle of tuberculin-tested milk, though it had been cleansed between the samplings.

142. Storrs and Burgwald. 1938. *J. Milk Tech.* 1, 18-35.

143. Leahy. 1938. *N. Y. Assoc. Dairy and Milk Insp.*, 12th Ann. Rpt.

144. Howell. 1939. *Med. Officer* 62, 218-219.

The second was very similar, the jug having been used for unpasteurized milk, then emptied and drained, but not wiped dry before being used again. No information was obtained regarding the third unsatisfactory sample.

Experiments were then made by which, first, one-third pint of pasteurized milk was placed in a jug which had previously contained raw milk and had not been drained or cleaned; second, in a jug which after being emptied of raw milk was drained for five minutes. Both were reported on as "raw or grossly underheated or contaminated with raw or improperly pasteurized milk." The Lovibond blue unit value was 10+ in place of a limit of 2.3 for properly pasteurized milk. When one pint of pasteurized milk was used in place of one-third of that amount the units were 3.7 and 3.1, respectively. Even a very thin film of milk remaining when a jug has been emptied and drained can thus be detected.

The phosphatase test in practical use has revealed situations which could have been discovered only with difficulty by other methods.¹⁴⁵ Raw milk as the cause of an outbreak of gastroenteritis was revealed by this test. Members of two camps became ill soon after meals at which the raw milk was served. The milk was supposed to have been pasteurized. Cans of raw milk were confused with cans of bulk pasteurized milk in a cooling room. The herds from which the milk used at the camps was obtained were found to contain cows with mastitis, six of which were slaughtered. The phosphatase test permitted accurate identification of the milk as raw milk. Otherwise this outbreak would have been attributed to contaminated pasteurized milk. The outbreak was attributed to a toxin in the raw milk. Excellent results with the phosphatase test have also been reported by Edwards and Nanji¹⁴⁶; Kay and Neave¹⁴⁷; Anderson, Herschdörfer, and Neave¹⁴⁸; Smith¹⁴⁹; and Geiger and Davis.¹⁵⁰

Effect of Bacterial Growth on Phosphatase Test. Bacterial growth was mentioned by Leahy, Sandholzer, and Woodside¹⁵¹ as a possible error resulting from hydrolysis of the bacterial nucleic acids. Tests were not advised on milk with microscope counts above 8,000,000 per ml. or standard plate counts above 2,000,000. Twenty-eight cultures of various bacterial species were tested for their ability to produce phosphatase when grown in milk. One strain of staphylococcus, five strains of *Aerobacter*, and three of *Klebsiella* were shown to produce a phosphatase reaction which showed slight activity at pH 9.0. Seven additional strains of various genera produced a false-phosphatase reaction. Similar observations were made by Hammer and Olson.¹⁵² *Pseudomonas* produced most phosphatase in sterile milk. Members of this genus and other organisms produced phosphatase in butter. An important point in this connection is the ability of *Pseudomonas* to grow at relatively low temperatures. In general, it appears that there

is less danger of phosphatase production causing positive tests in cheese than in butter, as many phosphatase-producing organisms are inhibited by the acid nature of the cheese.

On the other hand, Neave¹⁵³ stated that the test was not affected by bacteria in milk which produced reducing substances. It was also unaffected by the presence in milk of bacteria which produced reducing substances or which hydrolyze the substrate, sodium-phenyl-phosphate, unless the organisms are present in large numbers. Paley¹⁵⁴ also stated that growth and presence of various bacteria which would be common in milk did not reactivate or increase the phosphatase enzyme to an extent where it would interfere with the test. Neither did old sour milk. Storage of pasteurized milk for five hours at 37°C.(98.6°F.) did not show reactivation of the enzyme. Results of an investigation by Barber and Frazier^{154a} with cream revealed that a positive reaction to the phosphatase test developed in pasteurized cream after storage at from 4°C.(39.2°F.) to 10°C.(50°F.) for from 24 to 48 hours. Presence of phosphatase resulted from growth of Gram-positive, sporeforming bacilli in sterile skimmed milk. This is an important observation in appraisal of the phosphatase test. A false positive phosphatase test in properly pasteurized milk was also observed by Buck^{154b} who attributed it to a thermophilic organism to which he gave the name *Lactobacillus enzymothermophilus*. The phosphatase was extracted from the organism with distilled water. The enzyme was destroyed by heating at 85°C.(185°F.) for one minute. Production of phosphatase in milk at pasteurizing temperatures of 61.1°C.(142°F.) to 62.2°C.(144°F.) was observed to begin after a 90-minute holding period. Temperature, size of inoculum and the holding period are important factors. Buck stated that bacterial phosphatase is different from milk phosphatase. Where the phosphatase test is used for pasteurization control, it must be shown that the positive test is due to milk phosphatase which has not been destroyed.

Several modifications have been proposed by various investigators to make the phosphatase test more suitable for certain conditions. These have been compared by Burgwald and Giberson¹⁵⁵ and by Kay, Aschaffenburg, and Neave.¹⁵⁶ The former found the laboratory tests to be of about equal value for detecting irregularities in pasteurization of milk. As little as 1°F. variation in temperature, five minutes' variation in holding time, and one-tenth of one per cent added raw milk to properly pasteurized milk is detectable. Scharer's standard of .5 p.p.m. of phenol as an indication of proper pasteurization of 61.7°C.(143°F.) for 30 minutes seemed to be a little low. His test, however, has the advantage over Kay and Graham's and Gilcreas and Davis' that it requires a much shorter incubation time, and is less expensive in that acid-washed filter papers are not required. Scharer's improved rapid field test is nearly as effective as are any of the laboratory tests and has the distinct advantage of time and cost of oper-

ation in its favor, together with the fact that it can be made directly in the plant in a few minutes' time. BQC* was found to vary in sensitivity, and might be a factor in preventing the Scharer tests from being as sensitive as either Kay and Graham or Gilcreas and Davis tests. A photometer can be used in connection with any of these laboratory tests. Age of samples if kept so cold they do not sour has no effect on the test. Certain bacteria may be a factor with the Kay and Graham and Gilcreas and Davis tests if present in large numbers. This is rather remote, however, and the use of a control test would indicate the presence of any phenol-like substance which they might produce. Kay and his colleagues reported just about the same sensitivity. They found the test to be sensitive, accurate, and effective for controlling pasteurization by the holder process. The test in its appropriate modification is sufficiently sensitive to detect a drop in temperature of 1.0 to 1.5°F. if pasteurizing temperature is 61.7°C. (143°F.) for 30 minutes. If 62.8°C. (145°F.) for 30 minutes, a drop of 1.5°F. can be detected. They also reported that a reduction of 10 minutes in holding time could be detected but not five minutes with certainty. The presence of .2 to .25 per cent of raw milk in the pasteurized product and in many instances smaller amounts were detectable. These authors also found the test to be satisfactory for milk pasteurized for short times at high temperatures. In this bulletin are directions for the following modifications:

Scharer's¹⁵⁷ Rapid Phosphate Test for Detection of Inadequate Pasteurization of Milk and Milk Products. In order to shorten as much as possible the Kay and Graham phosphatase test, Scharer proposed a rapid test. His procedure is as follows:

"The buffered substrate (white) tablet contains the phenyl phosphoric ester, magnesium to catalyze the enzyme reaction and adequate buffer to make 50 ml. of the buffered substrate solution—sufficient for 10 tests. The BQC (yellow) tablet contains 2.6 bromoquinone-chloroimide and a stabilizer—sufficient for 30 or more tests. These tablets should be kept under refrigeration if possible.

"The buffered substrate tablets available commercially may develop varying amounts of phenol under certain conditions of storage, such as exposure to light or heat. Since the extraction technique is extremely sensitive, it is necessary to work with a phenol-free substrate; therefore the following procedure is utilized to remove any phenol and is recommended in all cases:

"Crush buffered substrate tablet in test tube, dissolve in five ml. of distilled water. Add two drops of BQC solution. Allow five minutes for color development, then extract the indophenol with 2-2.5 ml. of normal butyl alcohol. Allow to stand until alcohol layer has separated at top of tube. Remove alcohol layer with medicine dropper and discard. Dilute remainder of solution to 50 ml. This solution is then phenol free. Dissolve the BQC tablet in five ml. of 95 per cent ethyl or methyl alcohol. **DO NOT USE A DENATURED ALCOHOL.** Transfer to dropping bottle delivering 50 drops per ml.

* BQC = Bromo-quinone chloroimide.

157. Scharer. 1938. J. Dairy Sci. 21, 21-34; J. Milk Tech. 1, 35-38.

METHOD

"Add one-half ml. of sample to five ml. of buffered substrate. Shake briefly. Incubate for 10 minutes in a water bath at 36.7°C. (98°F.). (If no water bath be available, incubate in pocket for somewhat longer period.) Remove from bath, add six drops of BQC solution. Shake well immediately. After five minutes compare color with opaque standards.

"Properly pasteurized milk will be a gray or brown.

"Properly pasteurized cream will be a gray or white. Raw milk or cream will be an intense blue. The appearance of any blue is indicative of improper pasteurization, the degree of intensity of color being proportional to the seriousness of the condition.

"If only a trace of blue is found it may be hard to distinguish. In this event add two ml. of normal butyl alcohol (neutral). Invert the test tube SLOWLY at least 10 times and allow to stand. Rapid inversion will result in an emulsion being formed but if correctly performed the alcohol will separate clearly and will have extracted the indophenol formed by the test.

"The appearance of any blue or blue-green in this alcohol layer is indicative of improper pasteurization. In the absence of a properly pasteurized milk to be used as a control a boiled milk may be substituted.

"The test has been standardized with milk pasteurized—under laboratory conditions satisfying legal requirements—namely, a preheating period of one to five minutes and a holding period of exactly 30 minutes at 143°F. Under commercial conditions varying time of preheating and filling and emptying of tanks should be taken into consideration.

CAUTION

"All equipment should be thoroughly washed and rinsed before reuse. Avoid the use of phenolic resin bottle closures anywhere in the test. The BQC reagent is sufficiently sensitive to demonstrate the leaching of phenol from the resin by water.

"Both solutions decompose with age and should be stored under refrigeration or prepared shortly before use.

"A reagent blank should be made by adding three drops of BQC to five ml. of substrate. If a blue color results the substrate solution should be discarded. If the butyl alcohol procedure is utilized this reagent blank should be extracted with the alcohol."

Errors in this rapid test may result from decomposition of reagents. Scharer¹⁵⁸ recommended that fresh reagents be prepared daily. A co-operative investigation by 18 laboratories on identical samples under supervision of Gilcreas¹⁵⁹ indicated that the Scharer technic should be perfected further to attain maximum accuracy.

Other investigators have been satisfied with its accuracy. Roger¹⁶⁰ found it, or slight modifications of it, satisfactory on some 18,000 lots of pasteurized milk. The modification consisted of using amyl alcohol for a color solvent instead of normal butyl alcohol. Amyl alcohol with highly colored milk did not give so much yellow color that readings were confused. Roger believed the Scharer test to be reliable. Asschaffenburg and Neave¹⁶¹ found the test to be satisfactory. A few anomalies were found but were not considered to be significant. Some were due to the samples. Milk from animals suffering from mastitis tended to give abnormal results after pasteurization.

Since the phosphatase test is colorimetric, permanent standards have been suggested by several workers. Wyllie¹⁶² found standard blue solutions and blue tinted glass to be satisfactory. Unlike Wyllie, however, Gilcreas and Davis¹⁶³ found permanent standards prepared from inorganic colored solutions to yield accurate results when the essential condition of depth of color solution and a blue glass plate for reading the colors are observed. Variations from these conditions and lack of sensitivity of the eye to detect color differences will lead to errors in the results. The General Electric Company has developed a simple photoelectric colorimeter for use with the phosphatase test. It is called the "Luximeter." It is calibrated in terms of milligrams of phenol per .5 ml. of milk and also in terms of the enzyme units used for reporting the results of the phosphatase test modified by the Department of Health of the City of New York. Comparison of results of tests made with this instrument and those obtained with the permanent color standards agree. Its use will eliminate possible error owing to the human element and to fading or other changes in color standards.

A photoelectric cell was used by Tracy and Hahn¹⁶⁴ for determining the amount of phenol color in the phosphatase test. A raw-milk contamination of as little as .1 per cent can be detected easily provided a properly pasteurized sample of milk is available for reference. The method also gives satisfactory results in the detection of irregularities that might exist regarding time and temperature of pasteurization. Mercuric chloride tablets are suitable preservatives for milk to be examined by the phosphatase test.

Application of Phosphatase Test to Other Dairy Products. Necessity of pasteurizing other dairy products has prompted study of the application of the phosphatase test to them. Scharer¹⁵⁷ modified his test for ice cream. Since ice cream is usually pasteurized at temperatures which will destroy the phosphatase, the test is chiefly of value for detecting addition of unheated standardizing materials to the mix. Vanilla powder, vanillin or coumarin, fruit products, synthetic fruit flavors, or nut meats may introduce phosphatase or phenolic compounds. Scharer¹⁵⁸ also reported results with pasteurized cream. Cream is higher in phosphatase activity than the milk from which it came. Cream pasteurized at 71.1°C. (160°F.) for 15 seconds shows considerable phosphatase activity. It also appears that a greater amount of phosphatase is present in cream separated after pasteurization of the milk than in cream separated before pasteurization. In applying the phosphatase test to butter, the serum is removed and the usual procedure applied to it. The enzyme is concentrated in the serum and yields higher results than if the melted butter were used. Only slight phosphatase activity was found in butter made from cream pasteurized for 30 minutes at 61.7°C. (143°F.), but butter made from flash-pasteurized cream showed considerable phosphatase activity. High phosphatase activ-

ity was found in butter made from raw cream even after prolonged storage periods. In applying the phosphatase test to cheese, the cheese is first dispersed in the buffer solution and the equivalent of .5 gram of the cheese is used in the test. The enzyme was detected even after 18 months' storage with undiminished activity in cheese made from raw milk, but was absent in cheese made from milk pasteurized by both the holding and short time-high temperature methods. Processed cheeses usually gave negative results with the phosphatase test. When ice cream mix was pasteurized in accordance with usual practice, negative results were obtained with the phosphatase test. Chocolate milk, vitamin D milk, condensed milk, goat milk, and the like require no special treatment to determine whether they have been properly pasteurized. The laboratory test as well as the field test may be applied satisfactorily to these products. The accuracy of the phosphatase test, according to Perry and Doan,¹⁶⁵ is not significantly affected by homogenization, storage under refrigeration up to six days, development of oxidized flavor, or reinforcement with vitamin D.

The Amylase Test as an Indicator of Inadequate Pasteurization. This test was proposed by Leahy¹⁶⁶ and is based on the destruction of amylase in milk by heat. The technic is as follows:

Ten ml. of a well-mixed sample of the milk to be examined are pipetted into a test tube with precautions to prevent contamination with raw milk or with salivary amylase. At a recorded time .5 ml. of a sodium chloride-starch reagent is added, and mixed well by pouring from one test tube into another and back again. The mixture is then incubated at 30°C.(86°F.) for four hours. The sodium chloride-starch reagent is prepared by dissolving .4 gram of soluble potato starch and 20 grams of sodium chloride in 100 ml. of distilled water. At the end of the incubation period, two ml. of a reagent consisting of equal volumes of glacial acetic acid and chloroform are added, followed by immediate shaking with the thumb over the mouth of the tube. The addition of this strongly acid reagent, which changes the pH to about 3.4, terminates completely the activity of any milk amylase present. Thereafter, at a convenient time the tube is centrifuged at high speed for about 15 minutes. The clear supernatant liquid resulting from this treatment is poured into a test tube and the stage of starch hydrolysis effected by the enzyme determined by the addition of a few drops of a dilute iodine solution, such as a .5 N iodine stock solution diluted to about .005 N strength. This dilution should be prepared just before use, as dilute iodine solutions decolorize rapidly.

The stage of starch hydrolysis indicated by the color developed upon adding the dilute iodine solution is used as a measure of the temperature at which the milk was heated during pasteurization. A distinct yellow color denotes a strong action of the enzyme and, therefore, indicates the presence of raw milk. A distinct starch-iodine blue color shows that no amylase action has occurred, thus indicating the presence of milk which has been pasteurized properly at 61.7°C.(143°F.) for 30 minutes. A purple, red, or orange color denotes intermediate degrees of activity, and therefore indicates either improperly pasteurized milk or the admixture of raw with properly pasteurized milk.

Gilcreas and Davis¹⁶⁷ found that this test differentiated unheated from heated milk but it was not possible to determine major variations in treatment. The amylase content varies with the breed, diet, and period of lactation of the cow, and occasionally fresh milk was examined which contained so little amylase that it reacted in the test as though heated.

Effect of Pasteurization on Coliform Bacteria in Milk. Since these species are nonsporeformers and are generally destroyed by temperatures used in milk pasteurization, it was suggested that their presence in pasteurized milk indicated faulty procedures in the pasteurizing machine or contamination after pasteurization. Either of these situations would be objectionable. Results of many investigations have been reported and a survey of the literature leaves one in doubt about the pertinence of some of the conclusions which have been reported. Most strains of coliform bacteria are not sufficiently heat resistant to survive adequate pasteurization procedures when they are present in milk in reasonable numbers. When they are found, either excessive numbers were present in the raw milk or the milk was contaminated after it had been pasteurized. Attempting to determine whether *Escherichia coli* could be used as an index of adequate pasteurization, Swenarton¹⁶⁸ concluded that it could be used and proposed a standard—of all the .1-ml. portions examined not more than 20 per cent shall show the presence of *Escherichia coli*. Results of investigations by McCrady and Langevin¹³⁰ indicated that the plate count alone did not suffice for adequate control. Since coliform bacteria are seldom found in properly pasteurized milk, since even small numbers of them can be readily detected, and since they readily become established in open seams and fissures, and on unsterilized surfaces of equipment, the coliform test was considered to be a valuable supplementary control method. Large city plants, and probably small plants as well, can deliver to the consumer milk containing *Escherichia coli* in not more than 10 to 20 per cent of the one-milliliter portions.

On the other hand, Tiedeman¹⁶⁹ did not accept the coliform test as an index of adequate pasteurization, a position taken also by Frank of the United States Public Health Service. In France, however, Demigneux¹⁷⁰ stated that pasteurized milk in sealed containers should not contain *Escherichia coli* in one-ml. quantities when delivered to the consumer.

Gage and Stoughton¹⁷¹ found that in 55 per cent of thermal death point determinations made with *Escherichia coli* the cultures withstood 80°C. (176°F.) for five minutes. Ayers and Johnson,⁸⁷ using 174 strains isolated from human and bovine sources and from dairy products, found, as a general rule, these organisms have a low majority thermal death point, but that resistant strains occurred which survived heating for 30 minutes at 62.2°C. (144°F.). At 60°C. (140°F.) slightly over 50 per cent of the cultures remained viable; at 62.2°C. (144°F.) only 6.89 per cent survived. They stated that 62.2°C. (144°F.) was a critical temperature for *Escherichia coli*, but that heating to 65.5°C. (150°F.) should certainly destroy it. In view of these results, they advanced the opinion that presence of *Escherichia coli* in pasteurized milk which has been held for some time is not an indication of inefficient processing but of the multiplication of the few cells which survived. However, large numbers of the organisms present in

168. Swenarton. 1927. J. Bact. 13, 419-429.

milk immediately following pasteurization is evidence of inefficient and insufficient heating. Shippen¹⁷² isolated from pasteurized milks 31 strains of organisms of the *Escherichia coli* type. These were subjected to a temperature of 60°C.(140°F.) for 15 minutes in sealed glass tubes; the survivors, identified by their action when inoculated into sterile litmus milk and then into lactose broth, were heated at 61°C.(141.8°F.) for 15 and 30 minutes and so on by increasing degrees of heat until they no longer survived. Cultures of the strains killed at the initial temperature were subjected to decreasing degrees of heat until they survived. Of the 31 strains, 11 remained viable after 60°C.(140°F.) for 15 minutes; of these, one was killed only at 68°C.(154.4°F.) in 15 minutes and at 65°C.(149°F.) for 30 minutes. No culture of *Aerobacter aerogenes* resisted treatment at 60°C.(140°F.) for 15 minutes. These results confirmed the opinions of workers cited above on existence of heat-resistant strains of *Escherichia coli*. Shippen concluded that the presence of *Escherichia coli* in pasteurized milk is not to be interpreted as an index of improper pasteurization nor of subsequent contamination.

Finkelstein¹⁷³ also found 62.2°C.(144°F.) to be a critical temperature for *Escherichia coli* in milk. Since Brown and Gott¹⁷⁴ had stated that Endo's medium could be used to detect *Escherichia coli* in milk and the presence of this organism indicated undesirable conditions, Adams and Ward¹⁷⁵ examined certified and pasteurized milk in Detroit, and found that many of the lactose fermenters which appeared on Endo's medium belonged to the coli section of the colon-aerogenes group. Prompted by the work of Twiss,¹⁷⁶ Tanner and Dubois¹⁷⁷ observed the effect of heat on several organisms of the colon-typhoid group, among which was a strain of *Escherichia coli*. The strains survived 15 minutes' heating under conditions employed. Seeleman,¹⁷⁸ using two strains, found that they were destroyed in less than 30 minutes at 60 to 63°C.(140 to 145.4°F.). In England, Jenkins¹⁷⁹ stated that an effectively pasteurized milk should not contain *Escherichia coli*, and that the organism was a valuable index of pasteurization efficiency. Some American investigators do not agree with this. Such a position seems justified by the results of an investigation by Johnson,¹⁸⁰ who found that the temperature of 62.8°C.(145°F.) for 30 minutes was the critical temperature for *Escherichia coli*, but that some strains did actually survive pasteurizing times and temperatures. Johnson brought out the difference between "absolute" and "majority" thermal death points for organisms. Experiments on *Aerobacter aerogenes* showed a wide discrepancy between these temperatures. Johnson said, "Since all nonspore-bearing bacterial cells are similar to *Aerobacter aerogenes* in this respect, it is quite important that the selection of an effective pasteuriza-

tion temperature must be based on the 'absolute' thermal death point of pathogenic organisms, determined under laboratory conditions and in milk. Large scale efficiency tests are not necessary, and are apt to be misleading and wrongly interpreted so as to give a false sense of safety. Knowing the 'absolute' thermal death point of pathogenic organisms, the most valuable work for the future, in connection with pasteurization was predicted to be a study of the temperatures obtained in commercial practice, and the development of suitable instruments for determining that all of the milk in a given pasteurizing process is heated to a point which will provide a safe margin above the 'absolute' death point of pathogenic organisms."

Sadler and Middlemass¹⁸¹ found organisms like *Escherichia neapolitana* the cause of ropy milk. The strains isolated were killed at 63°C. in 10 minutes. Swenarton¹⁶⁸ studied 16 pasteurizing plants with respect to the *Escherichia coli* contents of the pasteurized milk. The pasteurizing temperature adopted as satisfactory is 61.7°C. (143°F.) for 30 minutes, with prompt cooling to 4.4°C. (40°F.). The term *Escherichia coli* is used broadly for lactose-fermenting (with gas), nonsporing aerobes. The test was found to be very helpful in checking up the performances of the different plants. Swenarton suggested the following standard: Five quantities each of .1 ml., to be examined, and not more than 20 per cent to show the presence of organisms of the *Escherichia coli* group. Apparently to guard against inequalities of sampling, etc., he adds, "Occasionally three or more of the five equal .1-ml. portions constituting a single sample may show the presence of *E. coli*. This shall not be allowable if it occurs in more than (a) 10 per cent of the standard samples when 10 or more samples have been examined; or in (b) one standard sample when less than 10 samples have been examined." This standard is a more or less arbitrary one, based on the findings from the best plants examined.

Despite the fact that Tanner and Windsor¹⁸² and Beavens¹⁸³ reported to the contrary, Swenarton¹⁶⁸ and McCrady and Langevin¹³⁰ have suggested the use of *Escherichia coli* determination as a reliable supplementary laboratory method for the control of pasteurization.

Coliform bacteria were present in about 94 per cent of raw-milk samples examined in Rochester, New York.¹⁸⁴ In every instance the number of colon bacilli decreased during the heating period, and only one per cent of the samples gave a positive test after the milk had been subjected to a temperature of 61.7°C. (143°F.) for 30 minutes. However, there was an increase during the bottling process. Conclusions were drawn that proper pasteurization destroys all of the coliform bacilli, that their absence from a sample of pasteurized milk gives evidence of not only proper pasteurization but also of proper sterilization of containers and utensils, and of proper technic in handling of the milk following pasteurization.

McCrady¹⁸⁵ later expressed the same opinion. The *Escherichia coli* test was stated to be a valuable adjunct to other methods for checking pasturi-

zation. This same position has been defended by Slack and Maddeford,¹⁸⁶ who stated that presence of *Escherichia coli* in pasteurized milk indicated either inadequate pasteurization or contamination. Absence of typical colon bacilli in a given volume of milk does not necessarily indicate proper pasteurization or even that the milk has been pasteurized at all, but the presence of typical colon bacilli in small volumes of pasteurized milk indicates some fault in pasteurizing, cooling, or bottling which demands investigation and correction. A similar position was taken by MacLean.¹⁸⁷ During a period of 18 months in 1935 and 1936, using the brilliant green bile (Difco two per cent) as a presumptive test for *Escherichia coli*, samples taken daily during normal plant operation were examined. The average of 7,460 tests of one-ml. milk samples and 2,66 tests of 10-ml. samples showed 99.6 per cent and 96.6 per cent, respectively, as negative. The average of the corresponding highest prevailing average plate counts was 9,470. The use of one-ml. samples in duplicate and a single 10-ml. sample of pasteurized milk is recommended as a satisfactory modified technic for plant control. MacLean's experience was that when the three tubes constituting this technic are all negative, the plate count of the sample is almost invariably below 10,000 colonies per milliliter. He suggested that his technic might be used as a means of reducing the number of plate counts and yet obtain a more satisfactory insight into the degree of plant sanitation.

Seventy-five cultures of coliform bacteria were isolated from milk by Graham.¹⁸⁸ Only one strain survived in the milk pasteurized at 62.5°C. (144.5°F.) for 30 minutes. More survived when the cultures were mixed. Graham considered the *Escherichia coli* test as not perfectly satisfactory but as good as any other bacteriological test is likely to be. Forty-six per cent of samples of pasteurized milk were found to contain *Escherichia coli* by Moffat and Mackay.¹⁸⁹ It was concluded that at some time incompletely pasteurized milk had passed into the pasteurizer. Bartram and Black¹⁹⁰ found no pasteurized milk with total counts under 1,000 containing coliform organisms, counts of colon-positive being 413 times that of colon-negative samples.

Various media and technics have been used for determining coliform bacteria in milk. Guittonneau, Mocquot, and Eyrard¹⁹¹ found the Dunham-Schoenlein medium most satisfactory. Ten-ml. portions of the medium were inoculated with 1 to .01 ml. of the milk to be tested and the tubes incubated at 41.5°C. (107°F.) for 48 hours. Indole was then determined by the Salzkowski or Ehrlich method. The dilution of the milk at which indole is detected is a measure of the coliform content. This method was considered a (very) satisfactory method for determining contamination of pasteurized milk, especially the type of milk known as "certified" pasteurized milk.

Yale¹⁹² compared solid with liquid media. The two solid media chiefly employed were Bacto-violet-red bile agar and desoxycholate agar. Both were found satisfactory, and, in general, red acid-forming colonies larger than .5 mm. could be assumed to belong to the coliform group. Plates give quantitative results and are most useful in studying plants. For samples of unknown origin broth tubes are sufficiently accurate. Gunsalus and Stark¹⁹³ compared results with brilliant green bile and formate ricinoleate broths and concluded that the brilliant green bile broth gave a slightly greater number of positive presumptive tests than the formate ricinoleate broth, but the brilliant green bile broth gave slightly lower percentage confirmation. In some cases, the positive presumptives were shown to have been produced by anaerobic, spore-producing rods.

It is obvious that some strains of *Escherichia coli* may pass through the pasteurization process. Heat resistance of this organism in milk is probably not constant, as shown by Lembke,¹⁹⁴ but is an expression of their physiological state at the time of heating. Wilson¹⁹⁵ believed that the coliform test might have some merit as a test for adequate pasteurization. Interpretation, however, might be influenced by the possibility of recontamination or presence of heat-resistant strains. Wilson's own experience seemed to indicate that the coliform test is applicable only to those milks which contain an appreciable number of coliform cells before pasteurization. A similar position was taken by Breuckner.¹⁹⁶

Barkworth¹⁹⁷ said that presence of coliform bacteria in pasteurized milk indicated a breach of plant hygiene. He suggested an Incubation Coliform Test which consisted of examination for coliform bacteria after incubation. This causes a few cells of coliform bacteria to develop into large numbers. Barkworth did not consider it necessary to identify the species. Resistant strains of coliform bacteria were of less importance to Rowlands and Provan¹⁹⁸ than the frequency of their occurrence in raw milk. If their occurrence is infrequent and the number surviving pasteurization is negligible in comparison with the number likely to be derived from contamination, then the test, when properly interpreted, can be applied as a measure of contamination during cooling and bottling.

The significance of results secured in the laboratory is difficult to determine. Practically any strain of *Escherichia coli* can survive pasteurization if the inoculum is large enough. Few of the investigators whose results are reviewed above paid any attention to numbers of cells which were present or to other factors which are known to be very important in heat-resistance work. If they had, it would have been difficult to know how many cells to have used, for the number ought to approximate normal contamination. When all information is analyzed, one is forced to maybe

consider presence of *Escherichia coli* in pasteurized milk as due to some break in plant hygiene, as Barkworth stated.

EFFECT OF PASTEURIZATION ON PATHOGENIC BACTERIA IN MILK

To make milk safe by destruction of pathogenic bacteria is the primary object of pasteurization of fluid milk. While not all pathogenic bacteria have been studied, it is quite probable that the results which have been secured with *Mycobacterium tuberculosis* hold for the others. Some results of investigations are contradictory owing, probably, to use of different strains under different conditions.

Effect of Milk Pasteurization on Mycobacterium Tuberculosis. It was the necessity of destroying this organism that forced health officials to pasteurize milk. Its heat resistance in milk determined the time and temperature that is used. *Mycobacterium tuberculosis* is contributed to milk by infected cows and consequently the milk must be treated to destroy the organism. Results of many experiments have been reported. There is some disagreement, as would be expected. Marshall¹⁹⁹ stated that 68°C. (154.4°F.) for 20 minutes destroyed the organism. In one series of five experiments, sterilized milk was infected with tuberculous material from different cows and then pasteurized by heating to 68°C. (154.4°F.), holding it at that temperature for 20 minutes, and cooling rapidly. In each experiment, one guinea pig for control was inoculated intra-abdominally with one ml. of the infected milk before pasteurization, and a number of guinea pigs were similarly inoculated with five ml. of the pasteurized milk. All of the control animals died from tuberculosis within a few weeks, while none of the 13 animals inoculated with the pasteurized milk developed the disease. As a temperature of 68°C. (154.4°F.) for 20 minutes did not produce a cooked flavor in the milk, and was shown by the experiments to kill the tubercle bacillus, Marshall argued that a lower temperature for pasteurization should not be adopted. Several experiments were also carried out in pasteurizing milk artificially infected with tuberculous material, at a temperature which would give the milk a cooked flavor. This was done by heating water surrounding small bottles of milk to the boiling temperature, removing the heat, and allowing the milk and water to stand for five to 30 minutes. Four guinea pigs inoculated with the unpasteurized milk developed general tuberculosis within a few weeks. The 12 inoculated with five times the quantity of pasteurized milk remained free from any trace of the disease.

Hammond²⁰⁰ reported that heating of milk to a temperature of 71.1°C. (160°F.) for 15 minutes insured destruction of the tubercle bacillus, reduced the number of other bacteria, and did not give a cooked taste. In 1900, Russell and Hastings²⁰¹ reported the results of experiments which did much to help settle the question of time and temperature of pasteurization. In five series of experiments, milk was inoculated with pure cultures

of the tubercle bacillus and heated at 60°C. (140°F.) in a commercial rotary pasteurizer. The time of heating in the different tests varied from five to 45 minutes. Control samples were unheated. The vitality of the organisms was tested by intraperitoneal injections into guinea pigs.

The conclusions from these series indicated that 10 minutes at 60°C. (140°F.) were sufficient to destroy the vitality of the tubercle organism so completely that large doses inoculated in the most susceptible portion of a very susceptible animal (guinea pig) failed to produce tuberculosis, while unheated samples of the milk and those exposed to 60°C. (140°F.) for five minutes produced the disease without exception.

In two series of experiments, a comparison was made of heating milk at 60°C. in the commercial pasteurizer and in open bottles placed in a water bath. In the latter case the milk remained in a quiescent condition and was exposed to the action of air which permitted a film to form on the surface. Where the milk was exposed in a quiescent condition, as in a glass tube or bottle, *Mycobacterium tuberculosis* was more resistant than where the milk was in a closed receiver and agitated. While *Mycobacterium tuberculosis* was destroyed in the commercial pasteurizer in 10 minutes, neither an exposure for this period, nor for 15 minutes, sufficed to destroy the same lot of organisms when the milk was treated in a quiescent condition at the same temperature in vessels to which the air had more access. It was recommended in order to thoroughly destroy any tubercle bacilli which it may contain, without in any way injuring its creaming properties or consistency, to heat it in closed pasteurizers for a period of not less than 20 minutes at 60°C. (140°F.).

Very high temperatures, 98°C. (208.4°F.) applied momentarily, did not always destroy *Mycobacterium tuberculosis*, according to Tjaden, Koske, and Hertel.²⁰²

According to Bang's²⁰³ experiments with tuberculous milk heated in a closed metal vessel, heating at 60°C. (140°F.) for one minute or less permitted pronounced tuberculosis by inoculation into the abdominal cavity of rabbits. Milk kept at 60°C. (140°F.) for five minutes also caused tuberculosis, but to a less extent. Heating for 15 minutes reduced the effect still more, only half the number of animals becoming tuberculous. Milk heated to 65°C. (149°F.) for a moment caused rather slight, but still recognizable, tuberculosis. On heating at 65°C. (149°F.) for five minutes the bacilli were killed. The same result followed heating for a moment, to 70°C. (158°F.), 75°C. (167°F.), 80°C. (176°F.), and 85°C. (185°F.). Feeding experiments with milk heated to 60°C. (140°F.) for two minutes gave negative results.

In case of continuous pasteurization, Bang considered 80°C. (176°F.) the lowest safe temperature for destroying tubercle bacilli, and believed that the Danish pasteurization law could be modified without danger to allow pasteurization at this temperature in creameries, the Storch color test being used to ascertain whether the skimmed milk had actually been exposed to this temperature.

Barthel and Stenstrom's²⁰⁴ experiments were different in that naturally infected milk from a cow in the last stages of tuberculosis of the udder was used. The secretion from the anterior or badly affected half of the udder was mixed with the milk from the posterior quarters of the udder, which were not yet as badly attacked by tuberculosis. It was found that a temperature of 65°C.(149°F.) for periods of five, 10, and 20 minutes was not sufficient to destroy the tubercle bacillus. Milk maintained at 70°C.(158°F.) for periods of five, 10, and 15 minutes remained in each instance tuberculous. The same results were obtained with experiments at a temperature of 75°C.(167°F.). At a temperature of 80°C.(176°F.) the milk remained tuberculous after exposure for periods of one, five, and 10 minutes. The reaction of the milk was shown to be important. Another important contribution came from Smith,²⁰⁵ who found that when tubercle bacilli were suspended in milk, they were destroyed in from 15 to 20 minutes at 60°C.(140°F.), the greater portion being killed in five to 10 minutes. Short periods of pasteurization showed that a temperature of 71.1°C.(160°F.) or above for one minute destroyed the virulence of bovine tubercle bacilli so that guinea pigs were not killed when inoculated with from two to five milligrams. Others have confirmed this work and these temperatures were accepted in the continuous process for some time. Smith's experiments were repeated by Hesse.²⁰⁶ He repeated them on a large scale, and a large firm of milk dealers was prevailed on to try the experiment of heating their milk to 60°C.(140°F.) for 20 minutes. The milk was heated in large vessels to 60°C.(140°F.) and was kept at this temperature for exactly 20 minutes, after which it was cooled as quickly as possible to a temperature of 8°C.(46.4°F.). During the heating of the milk it was stirred continually to prevent the formation of a pellicle on the surface, or the cooling of the superficial layer of milk. Hesse also enclosed cultures of tubercle bacilli in glass tubes,²⁰⁷ hermetically sealed, and placed these tubes in three vats of milk heated at temperatures of 60°C.(140°F.), 58°C.(136.4°F.), and 57°C.(134.6°F.), respectively. Inoculation experiments made on guinea pigs with the material contained in these vessels showed that all tubercle bacilli which were heated to a temperature of 60°C. were destroyed, while the guinea pigs which received the other cultures heated to temperatures of 58°C.(136.4°F.) and 57°C.(134.6°F.), respectively, developed cases of tuberculosis of a more or less generalized nature. It was believed that the sterilization of milk was best secured with the least changes in the composition and taste of the milk by subjection to a temperature of 60°C.(140°F.) for 20 minutes. Observations showed that by this treatment other organisms, including those causing cholera, typhoid fever and diphtheria, were also killed.

Levy and Bruns'²⁰⁸ experiments were carried out at temperatures below 100°C.(212°F.). The tubercle bacilli were obtained from pathological

tissue of bovine origin. From these experiments, it was concluded that when milk is exposed in a water bath to a temperature from 65°C. (149°F.) to 70°C. (158°F.) for a period of 15 to 25 minutes, all bacteria contained in the milk are destroyed. Svensson's²⁰⁹ experiments with an apparatus in which the milk was heated rapidly in a thin layer, to a temperature of 80°C. (176°F.) for two minutes, indicated that this was sufficient to destroy tubercle bacilli. This was not true, however, in experiments in which the temperature was 75°C. (167°F.). According to Russell and Hastings,²¹⁰ a temperature of 60°C. (140°F.) for 15 minutes is sufficient to destroy all nonsporulating pathogenic bacteria in milk without materially altering the flavor or appearance of the cream. When the method of pasteurization allowed the formation of a surface membrane, the destruction of *Serratia marcescens* (*Bacillus prodigiosus*), *Mycobacterium tuberculosis*, and a micrococcus was not so efficient.

Rullmann,²¹¹ however, reported that a temperature of 65°C. (149°F.) for 30 minutes was insufficient to destroy *Mycobacterium tuberculosis* in milk. According to Van der Sluis,²¹² a temperature of 80°C. (176°F.) was necessary for its distribution. He found that cells artificially added to milk were more resistant than cells which were in the milk when it was excreted. Russell and Hastings,²¹⁰ in further work, inoculated milk with cultures of tubercle bacilli of human and bovine origin and subjected them in sealed tubes to different degrees of heat, for varying lengths of time, the main object, however, being to determine the time required to destroy the bacilli at 71.1°C. (160°F.), with a view to applying the results to the continuous pasteurization of milk. Five series of experiments were made in each of which the virulence of the milk was determined by intraperitoneal inoculation of guinea pigs. The conclusion was drawn that a temperature of 71.1°C. (160°F.) or above, for a period of one minute, sufficed to destroy the virulence of *Mycobacterium tuberculosis* (bovis), so that the disease was not produced in experimental animals, like guinea pigs, inoculated with cultures ranging from two to five milligrams.

It was noted, however, that these laboratory experiments had been conducted under conditions more carefully controlled than was possible in commercial practice, and while the results were believed to lay a proper foundation for a safe and efficient treatment of milk, it was suggested that variations in the conditions of exposure, and also variations in the organism itself, must be studied before this new limit for the efficient pasteurization of milk in machines of the continuous flow type could be accepted unreservedly.

The reaction of the milk had been observed by several to have an important bearing on the question. Barthel and Stenstrom²¹³ coagulated milk with acid and showed that, in such milk, *Mycobacterium tuberculosis* (hominis) was not easily killed.

Bartlett²¹⁴ confirmed the work of earlier investigators that the holder process of pasteurization between 61.1°C.(142°F.) and 64.4°C.(148°F.) for 30 minutes destroyed the tubercle bacillus in milk. Raw milk from large mixing vats showed greater frequency of the presence of bacteria. Brown²¹⁵ heated 25 strains of *Mycobacterium tuberculosis*, which were pathogenic for guinea pigs, and found that those heated to 60°C. for 20 minutes and to 70°C. for five minutes were noninfectious. The former heating period was recommended. This same question was studied by Macaulay,²¹⁶ who used the ability of tubercle bacilli to cause tuberculosis in guinea pigs as the criterion whether pasteurization at 63 to 65°C.(145.4 to 149°F.) for 30 minutes destroyed the tubercle bacillus in milk. He carried out his experiments in a pasteurizing plant, dealing with 150 gallons per hour. Fresh milk was inoculated with tuberculous sputum, this milk was then placed in a thin-walled, brass, cylindrical box, the cover of which could be tightly screwed down, making a tight joint. After sterilizing the outside of this box, it was lowered into the holder of the pasteurizer where it was left for the required time. Macaulay found that the tubercle bacillus was destroyed by pasteurization at 63 to 65°C.(145.4 to 149°F.) for 30 minutes. Oerskov²¹⁷ heated tubercle bacilli in small tubes containing two ml. of the infected milk. The milk was heated at 63°C. for different intervals. After heating, the milk was inoculated onto Petroff's agar. The organisms survived 40 minutes' heating at 63°C.(145.4°F.) but were killed in 45 minutes. Anderson²¹⁸ found that about one-third of the guinea pigs inoculated with tuberculous milk which had been pasteurized at 63°C.(145.4°F.) for one-half hour died. This was confirmed much later by Grinsted and Plum.²¹⁹ White²²⁰ pasteurized naturally infected milk from cows with infected udders, and milk artificially inoculated with pure cultures, at 62.2°C.(144°F.) for 30 minutes, and found these conditions satisfactory for the production of a noninfective milk.

Brand²²¹ showed that pasteurization at 63°C.(145.4°F.) for 30 minutes killed all the pathogenic organisms but did not materially affect the keeping qualities. The findings were similar when human milk was pasteurized. An extensive study of the bacteriology of pasteurization was made by Jenkins.¹⁷⁹ He used a temperature of 62.2°C.(144°F.) for 30 minutes, with milk artificially infected with both the human and bovine types of *Mycobacterium tuberculosis*. Six experiments with culture strains tested under laboratory conditions at temperatures ranging from 62°C.(143.6°F.) to 63.3°C.(146°F.) showed killed or avirulent bacilli, as judged by guinea pig inoculations. Two experiments with naturally infected milk heated at 60°C.(140°F.) and 62.2°C.(144°F.) were equally satisfactory. One liter of tuberculous milk from a tuberculous cow was added to 50 gallons of milk

and subjected to pasteurization in a commercial plant. Two guinea pigs, inoculated with the milk and cream, respectively, before pasteurization, developed tuberculosis, while pigs inoculated after pasteurization remained healthy (killed after six weeks).

The results of a comprehensive co-operative investigation of this question under conditions which approached those in practice were reported by North *et al.*¹⁰ Their experiments were carried out in a factory which had been converted into a machine shop. Since it was impossible to obtain a sufficient amount of cultivated tubercle bacilli, the investigators had to resort to material from infected animals and human beings having severe tuberculosis lesions. Twenty-two tuberculous cattle were slaughtered and about 40 quarts of tuberculous material collected. About one gallon of discharges from 20 human being was also collected. These materials were then mixed, macerated and filtered, and diluted to make about 80 gallons. Certainly, such a procedure gave a potent inoculum with which to infect the milk. A number of tests were made with infected milk. Lack of space prevents a detailed review of the results.

They were finally summarized, and the statement made that the bovine type of *Mycobacterium tuberculosis* was destroyed in some tests in three types of improved commercial pasteurizers at 59°C.(138.2°F.) for 30 minutes. The authors mentioned regulations of the states of New York, Connecticut, and others that milk or cream shall be heated to a temperature of at least 61.1°C.(142°F.) and held at such temperature for 30 minutes or more. When taken in connection with the results of the tests just reported, North *et al.* believed that a temperature of 61.1°C.(142°F.) for 30 minutes gave an ample margin of safety. The report was criticized by several investigators who, as North and Park²²² stated, did not overlook the fact that in the first series of experiments the routine of operation and temperature control were not established and pathogenic bacteria were not killed. North *et al.* stated in their first report that this series was reported only as a matter of record.

In defense of the experiments and conclusions reported by North *et al.* in Public Health Bulletin No. 147, North and Park²²² claimed that the great variation in thermal death points reported for *Mycobacterium tuberculosis* in milk was due to faults in the heating equipment and its operation by the investigators. They again reported their belief that there was no material difference in resistance to heat between bovine and human strains of *Mycobacterium tuberculosis*, or between different strains of either species, or between the tubercle bacilli in naturally infected milk, tissue lesions, or pure cultures. The authors stated that the volume of data reported in Bulletin No. 147 in tests made at 61.1°C.(142°F.) and at 59°C.(138.2°F.) exceeded in quantity, by a large margin, the volume of data reported in any of the previous investigations, the results of which have already been accepted by bacteriologists. They believed that sufficient care had been used to justify the conclusion that *Mycobacterium tuberculosis* was killed at 59°C.(138.2°F.) when heated at 30 minutes and that a standard of

222. North and Park. 1927. Amer. J. Hyg. 7, 147.

61.1°C.(142°F.) for 30 minutes was a proper standard for pasteurization. They further stated that temperature standards which injured the milk were not necessary for the protection of the public health.

Michel²²³ showed that commercial pasteurization for 10 minutes at 63°C.(145.4°F.) or for five minutes at 65°C. is sufficient to completely destroy *Mycobacterium tuberculosis*. Meanwell²²⁴ pointed out that apparent differences might be due in part to greater virulence of the organism in naturally infected milk. He also considered the possibility of latent infections, and in his experimental work kept guinea pigs 100 days or more. He pasteurized separately, in special laboratory apparatus designed to heat every particle of the milk to a uniform and accurately determined temperature, naturally infected milk from three cows known to be suffering from tuberculosis of the udder. The milk from cow No. 1 was abnormal in appearance, a flocculent mass separating out on standing. The milk from the other two cows was normal, although slightly darker in color at times.

The centrifugalized deposit and cream from pasteurized, naturally infected milk was injected into guinea pigs with the following results: Two pigs, out of 284 injected, developed tuberculosis with milk treated at 62.8°C.(145°F.) for 30 minutes, and 60°C.(140°F.) for 20 minutes, respectively, whereas 10 pigs, out of 12 injected, developed tuberculosis with milk treated at 59.5°C.(138.8°F.) for 20 minutes. Coagulated material collecting on the cooler in some of the experiments was ground up with saline and injected into guinea pigs with the following results: Two pigs, out of 44 injected, developed tuberculosis with material from milk treated at 62.8°C.(145°F.) for 30 minutes and at 60°C.(140°F.) for 20 minutes. None of the six pigs injected with this material from milk treated at 59.5°C.(138.8°F.) for 20 minutes, developed tuberculosis.

Zeller, Wedemann, Lange, and Gildemeister,²²⁵ after extensive investigation on this subject, concluded that pasteurization, although bringing about a very great diminution of the infectivity of the tuberculous materials used in the experiments on animals, cannot be relied upon to kill off the organism completely. Important conclusions are that the continuous-flow type of pasteurizer is undesirable and that foam formation should be avoided as much as possible, because, in the milk foam, organisms are found to resist the conditions better than in the body of the milk. In a later publication these authors²²⁶ reported more data. Milk heavily infected with tubercle bacilli and fed to animals was rendered practically though not absolutely safe by low-temperature pasteurization. Of 32 young guinea pigs fed unheated tuberculous milk, 29 developed lesions. Of 30 pigs fed low-temperature, pasteurized milk, 25 showed no lesions. Of 16 calves fed unheated, tuberculous milk, 15 developed lesions. Of 28 calves fed pasteurized milk, in 18 no lesions could be found.

A similar experiment was made by Scharr and Lentz.²²⁷ Samples of milk were taken before and after 30 minutes' treatment at 60 to 63°C. (140 to 145.4°F.) in a standard commercial pasteurizing plant. The samples were fed to young pigs daily for a period of three months, and at the same time, the centrifuged deposit from certain of the samples was injected into guinea pigs. Definite tuberculous lesions were not found in any of the pigs or in the guinea pigs, whether they had received raw or pasteurized milk. A further series of similar experiments was undertaken with milk artificially infected with tubercle bacilli. The guinea pigs did not develop tuberculous lesions, whether they had been injected with the raw or heated milk, but almost all the young pigs were shown at autopsy to have lymph glands infected with tubercle bacilli, including those that had received the pasteurized milk. They concluded that 30 minutes' heating of milk at a temperature of 60 to 63°C. (140 to 145.4°F.) does not suffice to kill all tubercle bacilli. The experiments of Katrandjieff²²⁸ indicated that heating to 63°C. (145.4°F.) for 30 minutes was necessary.

Temperatures of 63 to 65°C. (145.4 to 149°F.), according to Rautmann,²²⁹ could be relied upon to destroy the tubercle bacillus. Proscholdt²³⁰ used these temperatures with milk which had been heavily seeded with tubercle bacilli. Control guinea pigs which received unheated inoculum developed tuberculosis, while pigs which received inoculum which had been heated at a temperature of 63 to 65°C. (145.4 to 149°F.) for 30 minutes, all remained healthy. In view of the various factors involved, Yanagisawa and Ida²³¹ believed a temperature of 63°C. (145.4°F.) was necessary for satisfactory pasteurization. Their conclusions were based on cultural tests and animal inoculations with both the human and bovine types of *Mycobacterium tuberculosis*.

The rate of death of this organism during pasteurization has not received much study. Corper and Cohn²³² found it to be logarithmic between the important range from 50°C. (122°F.) to 60°C. (140°F.).

It is most unfortunate that in most of the experiments, results of which are reported above, so few quantitative data were collected, and so little attention was paid to conditions of heating. The ample margin of safety, however, in selection of legal temperatures of pasteurization probably compensates for these defects in technic.

Proposals to pasteurize milk by the high temperature-short time method at 71.1°C. (160°F.) for 15 seconds made it necessary to determine that pathogenic bacteria would be destroyed. Workman⁴⁰ found it to be satisfactory with 17 strains of *Mycobacterium tuberculosis*. Other results are reported at other places in this chapter.

Eberthella Typhosa. At one time milk was a more important factor in spread of typhoid fever than it is today. While the number of milk-borne epidemics of typhoid fever has been lowered over the years, the curve

seems to have leveled off to about 30 epidemics a year in the United States. Many observations have been reported to prove the case for milk pasteurization with typhoid fever alone. This was well indicated by a striking report by Geiger and Kelly²³³ traced to a large dairy employing 20 men and milking 300 cows. Ninety gallons of milk were delivered to a substation in Richmond and 600 gallons to a substation in Berkeley. Investigations indicated that the milk had been infected by a man who had been ill a week before consulting a physician. Later clinical and laboratory data indicated that the illness was typhoid fever. The milk from this dairy was not pasteurized for one city, but was so treated for another. The authors call attention to the fact that "this constitutes a unique and unparalleled experiment with human beings—accidental of course—but demonstrating conclusively that pasteurization of milk supplies is an efficient method for preventing typhoid fever from food." Other data in support of such a statement have been collected by Jordan.²³⁴ Twiss²³⁵ has stated that *Salmonella paratyphi* and *Salmonella schottmülleri* often survived pasteurization under experimental conditions. Krumwiede and Noble²³⁶ denied this, and stated that 60°C.(140°F.) will destroy typhoid bacilli in milk in 20 minutes. They avoided possible error by completely submerging the container in the bath. The fact that the members of the colon-typhoid group are nonsporeformers might argue against their ability to survive pasteurization unless there were heat-resistant strains.

In the United States Naval Bulletin 19 (1923), 629-630, are reported results of experiments on thermal death points of *Eberthella typhosa* in heavily infected milk: at 54.4°C.(130°F.), some organisms survived one hour, but all cells were destroyed in from four to eight minutes at 61.1°C.(142°F.) to 62.7°C.(145°F.). In tests using large volumes of heavily infected milk, it was found that the organisms causing typhoid fever, paratyphoid fever, and diphtheria were killed in 10 minutes at temperatures between 60°C.(140°F.) and 62.7°C.(145°F.). Some of the tubercle bacilli survived 10 minutes, but were destroyed after 20 minutes' heating at 61.1°C.(142°F.) and 62.7°C.(145°F.). A similar study was carried out by Tanner and Dubois,²³⁷ who found that the usual methods of pasteurization would destroy the members of the colon-typhoid group if they were present in milk in not too large numbers. The laws of disinfection would indicate the possible survival of a few cells of these organisms if there were many cells in the raw milk. Anderson²¹⁸ studied the effect of heating milk to 63°C.(145.4°F.) for one-half hour on several strains of the typhoid, paratyphoid, and Gaertner group. He stated that *Escherichia coli* might be found which would survive this temperature and time. With most of the strains, such an exposure would destroy them. In four of the 15 cases in which streptococci were used in the experiments, the organisms were not killed by 63°C.(145.4°F.) for one-half hour.

Experiences of large cities during recent years has shown that pasteurization pays. Of course, there were probably other factors in part responsible for the steady decline in the typhoid death rate. Nauss,²³⁸ in discussing milk-borne typhoid fever in Illinois, presented graphic evidence of the value of pasteurization. North *et al.*,¹⁰ in their extensive study, heated strains from the typhoid-paratyphoid group. They stated that *Eberthella typhosa* was destroyed by momentary heating by a commercial heater to 60.6°C. (141°F.) and by one type of commercial holder at 55.5°C. (132°F.) for 30 minutes.

The data for the paratyphoid bacteria reflect quite well the facts for *Eberthella typhosa*. The conditions of the experiments seem to influence the results which are secured. For instance, Oerskov²¹⁷ heated milk in a test tube in a water bath at 63°C. (145.4°F.). It formed on the surface a ring composed of dried proteins. On account of this ring formation the paratyphoid bacillus may remain alive for 15 minutes to even two hours at the above temperature. However, if they are exposed to the action of the heat, they are killed in three minutes. The resistance of various strains heated to 63°C. (145.4°F.) in physiological salt solution, bouillon, and undiluted media was also determined. The strains studied withstood a temperature of 63°C. (145.4°F.) for from one to four minutes. The typhoid bacillus resisted only one minute; various strains of paratyphoid bacillus and Gaertner's bacillus two or three minutes; *Escherichia coli* 15 minutes. The pH has no influence between 6.0 and 8.0. Outside of these limits, the resistance diminishes.

Shigella dysenteriae (Bacterium dysenteriae). The characteristics of the dysentery organisms would indicate that they are just about as resistant to temperatures used in pasteurization as other members of the colontyphoid group. Doorenbos and Mulders²³⁹ heated cultures of *Shigella dysenteriae* to 50°C. (122°F.) to 60°C. (140°F.) and found that they were made sterile. Note should be made, however, that such cells are more easily destroyed in water than in milk. The Shiga type was killed in one minute in water at 60°C. (140°F.), while six minutes were required to obtain the same result in milk. For the Flexner type, Doorenbos and Mulders stated that the time required was, respectively, one minute and 10 minutes; for the Leiden type, one minute and 20 minutes. Rosenau²⁴⁰ stated that *Shigella dysenteriae* was somewhat more resistant to heating in milk than *Eberthella typhosa*. He stated that it sometimes withstood heating to 60°C. (140°F.) for five minutes. All cells were killed at 60°C. (140°F.) for 10 minutes; however, the great majority of cells were killed by the time the milk reached 60°C. (140°F.).

Pathogenic Streptococci. The possibility of infection with pathogenic streptococci in milk has made it necessary to determine whether such organisms are killed by pasteurization. Park²⁴¹ carried out an investigation on the thermal death point of a number of pathogenic streptococci from various sources in order to aid in the selection of a proper temperature for

commercial pasteurization. Previous to this time some work had been done, but not always with organisms of such sanitary significance. Ayers, Johnson, and Davis¹⁸⁵ reported that 60°C.(140°F.) for 30 minutes always destroyed 27 strains of pathogenic streptococci when heated in milk. A few other streptococci from similar sources survived this treatment and would, therefore, survive pasteurization. The number of cells heated in milk was not stated. Ayers and Johnson⁸⁷ also tested 139 cultures of streptococci from cow feces, the udder and mouth of the cow, and milk and cream. They stated that two classes of streptococci survived pasteurization: (a) Those which have a low majority thermal death point, among which are a few cells able to survive; (b) streptococci which have a high majority thermal death point. Some of the streptococci with which Ayers and Johnson worked were not killed in 30 minutes at 57.2°C.(135°F.), but none were able to withstand 60°C.(140°F.) for 30 minutes. These forms were not known to be pathogenic.

Park's²⁴¹ experiments were much to the point. He stated that in practically all cases, diseases transmitted through milk were caused by hemolytic streptococci. The strains which Park used came from septic sore throat, tonsillitis, scarlet fever, mastoiditis, glandular fever, erysipelas, and other sources. The details of technic used are given in a subsequent paragraph. Cultures from every one of 200 strains were killed by an exposure of 60°C.(140°F.) for 30 minutes. The majority of the strains were killed at 57.2°C.(136°F.) or less.

Davis²⁴² failed to find evidence that streptococci pathogenic for man could resist pasteurization temperatures (62.7°C.[145°F.]) for 30 minutes. He tested 98 strains and 74 hemolytic, pathogenic streptococci and found a resistance of 30 minutes at 60°C.(140°F.). Twenty of the 74 hemolytic strains came from milk and were not virulent. They resisted 68.3°C.(155°F.) for 30 minutes. The efficiency of pasteurization depends on several factors: (1) the heating of every particle of milk to the pasteurization temperature, and (2) holding it at that temperature for fully 30 minutes; (3) prevention of reinfection.

Zeller *et al.*^{225, 226} stated that streptococci from mastitis, although greatly diminished in numbers, were not killed completely. Such conclusions were also reached by Beckwith and Eddie.²⁴³ Whether in milk or in ice cream mix, hemolytic streptococci were resistant to pasteurization temperatures.

Park's²⁴¹ Method for Testing Thermal Death Point of Streptococci in Milk. Fill sterile vials with 10 ml. of sterile milk and place in a water bath, the water of which is somewhat higher than the desired temperature. When the milk in the vials and the water in the bath have reached the desired temperature, .05 ml. of a blood broth culture of the strain to be tested is injected into the milk and the vial stoppered by a rubber cork already heated to the same temperature. The stoppered vial should then be submerged in the water for the desired time. It should then be removed and the contents poured into an ice cold bottle and packed in cracked ice. The bottle with its contents should then be placed in the incubator at 37.2°C.(99°F.) for 42 hours. After incubation the milk should be tested on blood agar plates for viable Streptococci.

While most streptococci seem to be destroyed by pasteurization of milk, some have been reported occasionally to survive. This problem interested committees of the American Public Health Association²⁴⁴ whose reports indicate that some streptococci are sufficiently heat resistant to survive pasteurization. Weakly hemolytic streptococci were reported by Slanetz²⁴⁵ to be widely prevalent in pasteurized milk. He believed that the majority of these bacteria entered milk from the utensils. Since they were especially heat resistant, attention to utensils was recommended to eliminate them from the milk supply. Sixty strains were studied carefully, all of which could survive pasteurization temperatures. They formed alpha prime type of colonies on blood agar. Slanetz believed efforts should be made to keep such streptococci from milk. Whether these organisms survive or not depends on many factors, some of which were not considered by earlier workers. These have been reviewed in Chapter 2 under heat resistance of bacteria. Numbers of cells present and the time and temperature of heating are most important.

Corynebacterium diphtheriae (*Bacterium diphtheriae*). Milk has at times been the cause of diphtheria and, consequently, experiments were in order to determine whether pasteurization times and temperatures would destroy *Corynebacterium diphtheriae*. As early as 1894, Brieger and Fränkel²⁴⁶ reported that this organism was killed at 55°C.(131°F.) in 45 minutes. Welch and Abbott²⁴⁷ confirmed that result. Loeffler,²⁴⁸ however, stated that the organism was killed at 60°C.(140°F.) in 30 minutes. Moore and Hemlet (1906) came to the same conclusions reached by Park.²⁴¹ Rosenau stated that *Corynebacterium diphtheriae* was susceptible to heat in milk, and that it usually failed to grow after heating to 55°C., but that some cells might survive heating at 60°C. More recent work by North *et al.*¹⁰ seems to indicate that heating in a commercial heater to 53.9°C. (129°F.) for a very short time destroys the organism. Thus it seems that ordinary methods of pasteurization are probably able to destroy *Corynebacterium diphtheriae* in milk.

Brucella Species. These organisms are pathogenic for man and animals and may be transmitted in milk. It became necessary, consequently, to carefully determine whether they were killed by pasteurization. Rosenau²⁴³ stated that, as far as evidence then available was concerned, a temperature of 60°C.(140°F.) for 20 minutes was more than sufficient to destroy the etiologic agent of Malta fever in milk. It was stated that the organism was not killed by 55°C.(131°F.) for a short time; the great majority of cells was killed at 58°C., and at 60°C. all were killed. In 1928 Carpenter and Boak²⁴⁹ exposed cultures of human, bovine, and porcine species to temperatures of 60°C.(140°F.), 61.1°C.(142°F.), and 71.1°C. (160°F.) for various intervals of time. Tests for viability were made by cultures and animal tests, the guinea pig inoculation tests being more

reliable than the cultures. No cultures were viable after exposure to 60°C. (140°F.) for 20 minutes in milk. Later Boak and Carpenter²⁵⁰ confirmed these results as did Zeller *et al.*²²⁶ On the other hand, Bartram²⁵¹ stated that certain porcine strains of *Brucella abortus* might not be destroyed at 60°C. (140°F.) in 20 minutes, at 61.1°C. (142°F.) in 30 minutes, or at 62.7°C. (145°F.) in 15 minutes. Using a standard pasteurization outfit Murray, McNutt, and Purwin²⁵² found 62 to 63°C. (143.6 to 145.4°F.) when applied for three minutes to be sufficient to destroy both bovine and porcine varieties of the abortion organism. Their results indicated that the usual pasteurization temperature, as reported above, gave an ample factor of safety, providing the pasteurizer is operated in the proper manner. With the lid of the pasteurizer open, a much longer time exposure to this temperature is required and the results obtained are irregular and uncertain, in that viable organisms were recovered from the foam even after pasteurization for 30 minutes. The absolute necessity of a flush gate valve is also indicated, for in those experiments in which an ordinary faucet outlet was used viable organisms were obtained from the outlet after pasteurization for 30 minutes, whereas with the outlet closed by a stopper on the inside no living organisms remained after exposure for three minutes. The experiments emphasize the importance of carefully conducted operations in pasteurization if successful results are to be obtained.

Results of observations by Park, Graham, Prucha, and Brannon²⁵³ on two strains of *Brucella suis* in artificially contaminated whole and skim-milk samples suggested that efficient pasteurization destroys it in milk, preventing milk-borne porcine brucellosis. In whole-milk samples, containing 500,000,000 *Brucella* organisms per ml., sealed in glass tubes, both strains survived 30 minutes at 56.7°C. (134°F.) but were destroyed in 20 minutes at 60°C. (140°F.), in 15 minutes at 61.1°C. (142°F.), and in seven minutes at 62.2°C. (144°F.). They were more resistant to heat in milk samples in cotton stoppered tubes. *Brucella suis* remained viable for 30 minutes at 144°F. in milk containing 10,000,000 to 500,000,000 organisms per ml., but with the same time and temperature it was destroyed in milk containing 5,000 to 1,000,000 organisms per ml. Graham and Torrey²⁵⁴ later reported that no organisms causing brucellosis were found in 68 samples of pasteurized milk collected in Illinois. These samples came from various types of pasteurizers. That pasteurization will take care of these organisms was also indicated by Wiseman.²⁵⁵

Park's²⁴¹ experiments with *Brucella abortus* and *Brucella melitensis* indicated that 10 minutes' exposure in milk at 60°C. (140°F.) were sufficient to kill these organisms. Zeller's *et al.*^{225, 226} cultures of *Alcaligines abortus* were apparently a little more resistant, for an exposure of 60 to

63°C.(140 to 145.4°F.) for 30 minutes was necessary. The results of experiments of this nature ought not to be compared too closely. They are subject to a number of factors, such as number of cells, reaction of the milk, etc. It seems evident, however, that *Brucella melitensis*, and probably *Brucella abortus*, is probably destroyed by the ordinary methods of pasteurization. According to Murray, McNutt, and Purwin,²⁵² *Brucella suis* is easily killed by pasteurization.

The high temperature-short time method of pasteurization at 71.1°C. (160°F.) was found by Workman⁴⁰ to be satisfactory for destroying *Brucella* organisms. Seventy-four strains were used.

Vibrio comma (microspira cholerae). Rosenau²⁴⁰ stated that *Vibrio comma* (*Microspira cholerae*) was similar in heat resistance in milk to *Corynebacterium diphtheriae*. It was usually destroyed when the milk reached 55°C.(131°F.); only once did it survive 60°C.(140°F.) under the conditions of his experiments. Such results might be expected since this organism does not form spores.

Virus of Foot and Mouth Disease. The experiments of Zeller, Wedemann, Lange, and Gildemeister²²⁵ revealed complete destruction of the virus of foot and mouth disease by heating milk at 60 to 63°C.(140 to 145.4°F.) for 30 minutes.

CHAPTER 8

MICROBIOLOGY OF CREAM AND BUTTER

Microorganisms have an important role in the butter industry. Some are used to contribute desired flavor while others may cause deterioration and bad flavors. Quality depends on strict control of microorganisms, both those which are favored and those which are repressed. A few must be kept out of butter at all costs. Sorensen¹ stated that butter may be contaminated from impure water and be made to undergo serious spoilage. He recommended the use of chlorine-treated creamery waters. Linneboe² found that *Achromobacter putrescens* in water is often the cause of putrid butter. This organism was found in six out of 55 farm supplies. Other opinions on this question have been quoted in Chapter 4.

Microbiology of Cream. Owing to the fact that cream is frequently held on the farm and in creameries for long periods or shipped long distances, its microorganism content is important. The changes which may be brought about in it by various microorganisms will probably involve each of its constituents. When cream is not held at low enough temperature, some of these changes are quite undesirable. One of the more comprehensive investigations on microbiology of cream was carried out by Macy, Coulter, and Combs.³ Raw cream in every instance was found to be quite heavily seeded with microorganisms. Seventy-seven per cent contained ten million bacteria or more per gram; 48.9 per cent of cream samples contained over 1,000 yeasts per ml. and between 10 and 100 molds per ml. Results after pasteurization were in striking contrast. Molds were completely destroyed and yeasts were eliminated in 71 per cent of the samples. Each constituent of cream is susceptible to attack by microorganisms with formation of specific substances which are involved in deterioration.

Microorganisms which attack fat in cream have received considerable study because the products of such attack may be most undesirable. These organisms may act on the fat in cream or in butter. Deterioration of cream accompanied by marked lipolytic action on the butterfat at refrigeration temperatures was reported by Anderson and Hardenbergh.⁴ After several days the cream acquired a bitter flavor. The causal organism resembled certain members of the *Achromobacter* and *Alcaligenes* groups. It failed to grow above 35°C. (95°F.). Hydrolysis of fat was the main biochemical activity noted and was said to be of considerable economic importance. A new bacterium, for which the name *Bacterium lipidis* was proposed by Anderson,⁵ exhibited powerful fat-splitting action, weak action on protein, and none on sugars. It grew rapidly at refrigeration temperatures. A sharp throat irritation resulted from swallowing cream containing the

organism which was thought to be due to liberation of caproic, isocaproic, and caprylic acids from the milk fat. Spoilage of cream at low temperature is due mainly to hydrolysis of fat and protein which accounts for the rancid and bitter flavors. Lipolytic microorganisms are discussed in several other places in this book. They are becoming of great significance in the food industry.

The nitrogenous constituents of cream are also subject to attack by microorganisms. Powell⁶ found acid coagulating organisms to predominate in fresh raw creams but they were replaced during storage by acid-forming and acid coagulating-peptonizing groups. In freshly heated creams the peptonizing groups increased from 25 per cent in cream held at 63.8°C.(155°F.) to 75 per cent in cream held at 85°C.(185°F.). Objectionable bitter flavors developed in raw creams shortly after storage. Flash pasteurization at 73.9°C.(165°F.) prevented the formation of these flavors during a 10-day storage period. In the late spring and summer flash pasteurization at 68.3°C.(155°F.) produced fine-flavored creams storable for 10 days. Pasteurizing temperatures above 73.9°C.(165°F.) imparted objectionable heated flavors to cream. Presence of both proteolytic and lipolytic bacteria might mean rapid deterioration of cream if it were not adequately refrigerated.

In view of meager information on the bacterial content of market cream, Robinton, Borman, and Mickle⁷ examined 523 samples of raw and pasteurized cream; many were substandard according to "tentative standards." They recommended in addition to incubation at 37°C.(98.6°F.) for 48 hours, incubation at 8°C.(46.4°F.) for four days. Robinton, Borman, and Mickle were also inclined to minimize the importance of thermophilic bacteria in cream. A comparative study of methods later caused these investigators to conclude that the clump count under the microscope was the most satisfactory method, especially if, after pasteurization, the phosphatase test is made and if coliform bacteria are enumerated. They observed sporeforming bacteria in cream which survived pasteurization for 30 minutes and which developed rapidly in cream at 20°C.(68°F.). They do not develop on the old "standard methods agar" but can be counted by the microscope method. Pin-point colonies have been found on plates made from cream as well as on plates made from other dairy products. O'Droma⁸ found them to be the cause of high counts and attributed them to *Streptococcus thermophilus*. The organism was slightly hemolytic and showed appreciable heat resistance.

Coliform Bacteria in Cream. While the sanitary significance of coliform bacteria in cream may be open to debate, these organisms are known to cause rapid and serious deterioration in cream. One hundred and twenty-eight strains of coliform bacteria isolated from cream by Pont,⁹ when carefully differentiated by acceptable methods, proved to be 76.5 per cent

8. O'Droma. 1940. J. Dairy Res. 11, 37-42.

9. Pont. 1935. Idem 6, 148-152.

typical *Escherichia coli*, 11 per cent *Aerobacter aerogenes*, and 12.5 per cent intermediates. The two latter groups were similar in their effect and produced more serious deterioration in quality than typical *Escherichia coli*. Crossley¹⁰ also found coliform bacteria in clotted cream. They were believed to result from contamination during processing.

METHYLENE BLUE REDUCTION TEST FOR CREAM

Less attention has been given to the possibility of using the methylene blue reduction test for grading cream than for grading milk. Macy¹¹ carried out a most comprehensive investigation in which he found that a triple-strength methylene blue solution had to be used. Macy's results showed that the reduction time was inversely proportional to the number of bacteria in cream as determined by the agar plate and microscope methods. The test was said to be useful for sweet cream having acidity less than .21 per cent. It is not adaptable to sour cream. Rapid disappearance of color indicates a high number of bacteria. Barnum¹² used a triple-strength methylene blue solution for cream instead of the one recommended in *Standard Methods of Milk Analysis* then in use. Presence of fat did not significantly influence reduction time.

Macy's¹¹ Method for Methylene Blue Reduction Test on Sweet Cream. The procedures were given as follows:

APPARATUS NEEDED

1. Pipette or metal dipper having a capacity of ten (10) milliliters (10 cubic centimeters).
2. Burette, graduated to one (1) milliliter, and apparatus stand provided with burette clamps; or, pipette graduated to one (1) milliliter.
3. Test tubes, thick-walled, $\frac{5}{8}$ " x 6" or $\frac{5}{8}$ " x 5". (It is often convenient to grind an area $\frac{1}{2}$ " square on the upper portion of the tube by means of an emery wheel so that each tube may be marked easily with a lead pencil. Such markings may be erased when the tubes are washed.)
4. Cork or rubber stoppers for each tube.
5. Water bath. (The size depends upon the number of tests made.)
6. Wire racks for test tubes. Single or double row type is advisable.
7. Alcohol lamp, gas burner, or electric hot plate.
8. Methylene blue tablets. Standard tablets are manufactured by the National Aniline and Chemical Company, Inc., New York City, and are available at creamery supply houses.
9. Thermometer. (Centigrade or Fahrenheit.)
10. Graduated cylinder.

COLLECTION OF SAMPLE

Collect a ten (10) milliliter sample of cream in weigh-room, directly from patron's can if possible, by means of a metal dipper or a pipette. Place sample in a clean, boiled or sterilized test tube. Number properly. Place boiled or sterilized stopper in tube. Set tubed sample in rack in ice water bath until all samples are collected or until methylene blue solution is added. Rinse dipper or pipette thoroughly in cold water and then in boiling water before taking the next sample.

10. Crossley. 1939. Agr. Prog. 16, 38-44.

11. Macy. 1934. Minn. Agr. Expt. Sta. Bull. 310.

12. Barnum. 1932. Internatl. Assoc. Dairy and Milk Insp. Ann. Rept. 21, 192-196.

ADDITION OF METHYLENE BLUE

As soon as possible after the samples are taken, add one milliliter of the methylene blue solution to each sample of cream. Mix thoroughly. (It is usually convenient to collect a number of samples before adding the solution in order to simplify and to expedite the reading of results. However, the samples must be kept cold during the interval before making the color test.)

The methylene blue solution is prepared by dissolving three methylene blue tablets in 50 ml. of boiling water. Then add sufficient cold water to bring the total volume to 200 ml. Three tablets are necessary for cream, while one is sufficient for milk.

Warm the cream samples to 37°C.(98.6°F.) immediately after adding the solution. (Record time when that temperature is reached. This is the starting point for observations on the time required for the disappearance of the blue color.) Keep tubes in water bath or incubator at that temperature until the samples are decolorized. (The alcohol lamp, gas burner or electric hot plate may be helpful in maintaining a constant temperature of the water bath.) The samples should be kept away from light during the period of observation.

READINGS

Observe the tubes at intervals of ten minutes or less during the first hour. After that readings may be made each half hour.

Record the time required for the blue color to disappear from each sample. This is called the "reduction time."

GRADING THE CREAM

The samples may be graded, on the basis of reduction time, according to the following classification:

GOOD: not decolorized in 5½ hours.

FAIR: decolorized in less than 5½ hours, but not less than 2 hours.

POOR: decolorized in less than 2 hours, but not less than 20 minutes.

VERY POOR: decolorized in 20 minutes or less.

Molds in Cream. Owing to the nature of cream it may contain a variety of fungi. *Oidium lactis* (*Oospora lactis*) is probably the best known species especially from sour cream. It grows on the surface with a characteristic velvety appearance. According to Elliker¹³ it enters milk and cream in dust, dirt, manure, and from carelessly washed utensils. Some strains grow at as low as 4.4°C.(40°F.), others at as high as 37.7°C.(100°F.), but ideal temperatures approximate 23.8°C.(75°F.). It was found to be destroyed by proper pasteurization. Growth of *Oidium lactis* is favored by a slightly acid reaction but is retarded or inhibited by high acidity, lack of air, presence of salt, and possibly by propionic acid or its salts. Its presence in butter with yeasts and other molds indicates unclean utensils. Frequent delivery of cream prevents the mold problem because it does not have time to develop. When the cream is used for buttermaking, high mold content causes many molds in the butter. Fouts¹⁴ found that *Oidium lactis* and bacteria were somewhat inhibited by butter-culture organisms in cream. *Mycotorula lipolytica*, however, showed increased growth in presence of such organisms. Even in high-acid cream lipolysis was extensive enough to be of considerable importance. Some of the fungi used were inhibited by addition of excessive amounts of lactic acid. Various opinions exist with respect to the possible significance of *Oospora lactis* in cream. Thom¹⁵ considered the fungus to be a common and offensive contaminant

13. Elliker. 1941. Natl. Butter and Cheese J. 32, 8.

14. Fouts. 1940. J. Dairy Sci. 23, 303-306.

15. Thom. 1935. Fundamentals of Dairy Science. Associates of Rogers. Second ed.

which develops mostly in the cream layer of old milk. It causes serious deterioration especially when many lots of cream are blended. A few practical dairy technologists have expressed a different opinion. Parfitt and Galema,¹⁶ however, believed that molds in sour cream produced products which were undesirable in the manufacture of butter. Better butter is made when they are absent.

Statements are common in dairy products literature that it is almost impossible to produce dairy products, cream in this case, without mold contamination. This may be true for very slight contamination but heavy contamination undoubtedly indicates carelessness either in cleaning utensils or in handling the product itself. Wildman¹⁷ stated that farmers should be able to produce cream, even in the summer, relatively free from mold growth. Concerning the presence of mold mycelia in butter Wildman stated that an occasional mold spore in the cream would probably not cause mold mycelia to be present in sweet cream butter. He was unable to show the presence of mold mycelia in such butter of known history. However, in the case of butter churned from sweet cream of varying ages and degrees of soundness the facts were different. In a survey at several creameries producing butter from sour cream during the month of June Wildman found that the mycelia contents varied from 22 to 100 per cent, the latter being the highest obtainable by the method used. As he viewed the situation the problem was to determine the relation of the presence of mycelia in butter to the type of cream used. In general he found that unsound cream might be expected to be moldy. Products of sound sour cream involves strictly clean utensils, low temperatures, and fresh cream. Old cream during the summer was usually in the high-count range, while fresh cream naturally decreased the mold problem. Clean utensils and a storage temperature of 15.5°C. (60°F.), according to Elliker and Brown^{17a} will keep mold development low in cream over a storage period of four days. Temperatures as high as 21.1°C. (70°F.) were said to be possible over a four-day period if utensils are kept scrupulously clean and milk or cream protected from dirt and dust.

Wildman's¹⁸ Macroscopic Method for Estimation of Mold in Cream. In addition to the microscope method, Wildman proposed a macroscopic method which could be used by creamery operators for detecting moldy cream in those cases where the mold had been stirred into the cream.

Method "A":

EQUIPMENT AND REAGENTS

- (a) Teaspoon—five ml.
- (b) Methylene blue-borax solution—Dissolve 30 grams of sodium borate and 10 methylene blue tablets (as used for reductase test) in 1 liter of water.
- (c) Test tube—5-6".
- (d) Shallow tin pie pan—Approximately 7" in diameter.
- (e) Scalpel.

PROCEDURE

Measure out five ml. of cream, preferably warm as for Babcock test sampling, in the teaspoon and place in the test tube. Add 15 ml. of hot (90°C.) methylene

16. Parfitt and Galema. 1931. Amer. Creamery and Poultry Rev. 71, 462-464.

17. Wildman. 1939-1940. Amer. Butter Rev. 1-2, p. 10.

17a. Elliker and Brown. 1942. Purdue Univ. Agr. Expt. Sta., Bull. 465.

18. Wildman. 1937. J. Assoc. Off. Agr. Chem. 20, 93-100.

blue-borax solution, using a portion to rinse all the cream from the teaspoon into the tube. Shake the mixture well and pour into the pie pan. Tip the pan back and forth until all mold present has agglutinated into blue-stained masses. (In samples containing much mold, the flocculation occurs immediately. In most cases of non-moldy sour cream, no blue flecks will form.) For purposes of comparison, collect the mold into a disk with a scalpel, and measure and designate the diameter roughly by the following scheme:

Diameter of clot	Approximate area
mm.	sq. mm.
9.5	70
5.5	24
3.5	9
2.5	4
1.0	1

At the present time the following simpler method of examination is used:
Method "B":

EQUIPMENT AND REAGENTS

- (a) Beaker—50 ml.
- (b) Methylene blue-borax solution—Prepare as directed in Method "A."
- (c) Perforated funnel—Made from perforated brass, No. 26 gage, having approximately 625 holes per sq. in., each hole being .02" in diameter. A circular disk 1.5" in diameter is cut, and from it is removed a 45° sector. The edges of the remaining disk are bent together until they meet, and are then soldered. To this funnel is soldered a .5" collar.
- (d) Scalpel or dissecting needle.

PROCEDURE

Weigh out five grams of cream into the beaker and add 15 ml. of the hot methylene blue-borax solution. After agitating the beaker for three minutes, pour the mixture through the special perforated funnel. Add more hot methylene blue-borax solution to wash any mold clots into the apex of the funnel. By means of a dissecting needle, level off the top of the mold until it forms an inverted cone and then measure the diameter of the base formed thereby (mm.).

Significance of results secured with the above method was investigated by determining the mold content of 44 individual samples of butter churned from cream, the mold content of which had been determined with macroscopic methods. Cream with low mold content yielded butter with low count. Examination of many samples of cream showed higher mold content in the summer and fall months. In order to determine the effect of churning on the mold content of butter, a sample of moldy cream was churned. It yielded butter and buttermilk in the ratio of two to three. The mold count on the butter was 76 per cent, and only four per cent on the buttermilk. These results seemed to indicate that churning instead of reducing the amount of mold actually concentrated it in the butter.

Ropy Cream. Microorganisms causing ropiness in cream seem to be little different from those which cause the same defect in milk. Rodenkirchen¹⁹ found ropy cream to be due to *Aerogenes aerobacter* and another species having much in common with *Sarcina aurantica*.

Canned Cream. In an outbreak of bitterness in canned cream the cause of the defect was found by McMaster²⁰ to be a short, sporeforming rod

19. Rodenkirchen. 1939. Zentbl. Bakt., Pt. 1, 144, 187.

20. McMaster. 1933. Ann. Rpt. Fruit and Veg. Res. Sta., Univ. of Bristol. 71-74.

which was similar to but not identical with *Bacillus cohaerens*. The spores when suspended in milk did not survive exposure to 115.5°C. (239.3°F.) for 12.5 minutes. Increasing the processing temperature prevented development of the bitterness. A bitter flavor and a thin consistency in canned cream was found by Nichok, Howat, and Jackson²¹ to be due to three organisms, all belonging to the *Bacillus subtilis* group but showing various cultural differences. A large number of normal tins were inoculated with these three strains and the abnormal conditions reproduced, although the three strains were not equally effective. The changes did not readily occur at room temperatures, but occurred rather slowly at 25°C. (77°F.) (three weeks or longer), while most of the tins held at 32°C. (89.6°F.) and 37°C. (98.6°F.) showed thin contents with bitter taste at the end of two weeks. The organisms were always recoverable but often in surprisingly small numbers. The spores of these strains resisted temperatures up to 120°C. (240°F.) for as long as 40 minutes. Bitterness and thinning usually went together and chemical analyses showed that they were associated with breakdown of the protein.

Cream canning presents problems which are somewhat different from those of other dairy products. Loveless²² studied the rate of heating and the viscosity of cream. The viscosity changed considerably during the first day after sterilizing, and continued to change at a decreasing rate over a period of many days. Variations in agitation seem to be the cause of variations in viscosity. The use of a preheating temperature of 140°F. (instead of 110°F. as generally used in commercial practice) produces an increase of about 50 per cent in viscosity after sterilization and reduces the tendency of the cream to form grains by coagulation of the protein, thus giving a smoother cream.

Whipped Cream Products. Whipped cream is a popular food on the American Market. Up to the present time it has been whipped mechanically with beaters, the success of the operation being dependent on numerous factors which have been reviewed by Sommer.^{22a} Studies on the microbiology of cream by various investigators whose publications are listed elsewhere in this paper, and especially by Robinton, Borman, and Mickle⁷ indicate that market cream may not always be a high-grade product.

A new method of whipping cream which departs from the older mechanical methods and contributes markedly to a sanitary product has been developed. This new method, best represented by "Instantwhip," involves charging the cream with an innocuous gas under pressure in a special container.^{22b} The cream is whipped as it blows through the valve of the pressure bottle. Getz, Smith, Tracy, and Prucha^{22c} stated that whipping takes place by physical-chemical rather than by mechanical means. This method involves use of nitrous oxide at 150 pounds pressure and results

22a. Sommer, H. H. 1938. *Market Milk and Related Products*. Sommer, Madison, Wis.

22b. Getz. 1942. U. S. Patent 2,294,172. Aug. 25, 1942.

22c. Getz, Smith, Tracy, and Prucha. 1937. *Food Research* 2, 409-428.

in a product of about 300 per cent overrun. The sanitary features of such a product should be apparent to those who are familiar with the problems of handling whipped cream at many places where it is served. In a survey Prucha ^{22d} observed both insanitary handling and development of bad flavors in whipping cream, dispensed by hand dipping.

The following table summarizes some of the many data which Prucha published :

Average Logarithmic Bacteria Counts of Whipped Cream
From Five Cities When It Was Served

City	Instant Whip	Hand-dipped
	Per gm.	Per gm.
City 1.....	770,000	5,100,000
City 2.....	44,000	700,000
City 3.....	225,000	1,190,000
City 4.....	200,000	5,400,000
City 5.....	No samples	590,000

It is evident that hand-dipped whipped cream has many more bacteria than whipped cream prepared and served by the new method. This is due largely to poorer raw materials, contamination during handling and serving, and the time which intervenes between manufacture and serving. A distinct advantage of whipped cream prepared according to the new method is the fact that it may be pasteurized in the closed special container. Such methods of pasteurization of a dairy product in the final container have been sought by dairy technologists for many years. Prucha ^{22e} has collected many data secured with *Eberthella typhosa*, *Shigella dysenteriae*, *Brucella melezensis*, and others, all of which show that pasteurization in the special closed container destroys all of these pathogenic bacteria and yields a dependable, safe product. Pressure of the gas itself also helps to destroy bacteria during storage and the cream was observed to keep much better under these conditions. This process may be looked upon as another distinct advance in distributing dairy products under safe and sanitary conditions.

Pasteurization of Cream for Butter Making. Cream is pasteurized before being made into butter to reduce the general bacterial flora before butter culture is added, to destroy microorganisms which would deteriorate butter, and to destroy pathogenic bacteria. Butter has been known to cause epidemics, and any step which would destroy disease-producing bacteria would help to make life safe. Pasteurization of cream may also destroy enzymes which might deteriorate butter. Hammer ²³ observed that vat pasteurization of sour cream at 60°C.(140°F.) to 62.7°C.(145°F.) for 20 minutes sometimes left large numbers of living bacteria, although the percentage killed was high. Better destruction was observed by flash pasteurization at 82.2°C.(180°F.) to 85°C.(185°F.). Only small numbers of bac-

23. Hammer. 1914. Iowa Agr. Expt. Sta. Bull. 156.

teria survived. Hammer's results in these experiments did not indicate as great benefits from pasteurization as later investigators reported. Butter made from raw cream showed as good keeping quality as butter from pasteurized cream. Hunziker *et al.*²⁴ reported that butter made from pasteurized cream brought a higher price than butter made from raw cream. Contrary to the results of Hammer, quoted above, Hunziker and his colleagues found the holding process of pasteurization at 62.7°C.(145°F.) to show greatest bacteria-killing power while the flash process at 85°C.(185°F.) gave erratic results. That keeping quality of butter is improved by pasteurization was shown by the fact that pasteurized cream yielded better butter.

It is not a simple matter to relate butter quality to any one factor such as cream pasteurization. Wide variations in resistance of bacteria to heat influence the results of applying heat to cream. According to Parker and Brengman²⁵ optimum pasteurization methods for use under various conditions are not known. Besides reduction in the general bacterial flora by pasteurization of cream there is destruction of specific microorganisms which may cause development of bad butter. Prevention of development of fishy flavor in butter was accomplished by Platon and Olsson²⁶ by heating the cream to 85°C.(185°F.).

Resazurin Test for Determining the Quality of Pasteurized Cream. This test has been found to be satisfactory for judging the quality of various dairy products. Chilson and Collins²⁷ reported that it was satisfactory for determining quality in pasteurized 20 or 40 per cent cream. When such cream was stored for several days at less than 4.4°C.(40°F.) the resazurin reduction time did not indicate fully the increase in plate counts. Collins *et al.*²⁸ applied the resazurin test to raw cream. Samples which had resazurin pink tests of two hours or more had microscope counts averaging logarithmically 150,000 to 300,000 bacteria per ml. Jenkins²⁹ made the test by adding .1 ml. of a .05-per cent solution of resazurin dye to 10 ml. of pasteurized cream and incubating at 36.7°C.(98°F.). Cream with a reduction time of less than six hours often exceeded the legal limit for bacterial numbers (40,000 per ml.). Cream with a reduction time of from six to seven hours, had an average plate count of 17,000 bacteria per ml. and was free from customer complaints.

Phosphatase Test Applied to Cream. Most cream to be used for butter making is pasteurized by the "flash" method. Scharer³⁰ said there was some evidence to show that a greater amount of phosphatase is found in cream separated after pasteurization than when separation precedes pasteurization. He explained this by saying that inactivation of the enzyme was a logarithmic function of time and temperature, the enzyme not being

completely inactivated at 61.7°C.(143°F.) in 30 minutes, and that this small amount of enzyme is subsequently concentrated in the cream. Raw cream was said to contain several times the phosphatase found in raw milk. Cream heated to 71°C.(160°F.) for 15 seconds showed considerable phosphatase. The main object of an investigation by Shadwick and Parker³¹ was to study the utility and limitations of the phosphatase test for this product. A laboratory flash pasteurizer was devised. Practically, there was no holding time as this was only about 30 seconds, including the heating time. On the basis of agar plate counts temperatures of 82.2°C.(180°F.) or above gave satisfactory (about 99 per cent) bacterial reduction. At 85°C.(185°F.) or higher temperatures negative phosphatase reactions were obtained with the original test or various modifications, such as the Scharer short method. At 180°F. negative results were obtained by the modified Scharer short method and by the methods of Kay and Graham requiring two and one-half and eight hours of incubation, but the results were doubtful using the 24-hour incubation period. At 79.4°C.(175°F.) positive phosphatase results were obtained with most methods and positive with all methods below 175°F. The authors discussed various factors which may possibly vitiate the phosphatase test findings, including the possible stimulation of phenol production in butter.

No relation was found by Parfitt, Brown, and Shadwick³² of phosphatase value of butter to its yeast and mold count, total bacterial count, and keeping quality as measured by drop in score. Agreement secured between two laboratories on identical samples of butter was closer with the short methods than with the one-hour method. A higher percentage of phosphatase positive reactions was found in cream from flash systems of pasteurization than from plants using vat systems. However, some plants which were flash pasteurizing consistently yielded negative phosphatase reactions which indicate that the process was not at fault. Owing to possibility that the enzyme is concentrated in butter, and because of the lack of knowledge concerning its partition in butter from cream, further studies on this point are indicated. It has been found that under the conditions which butter is marketed a significant number of samples will react negative when fresh and positive after receiving treatment comparable to commercial methods of distribution.

Laboratory pasteurization of 20 and 35 per cent cream by Caulfield, Nelson, and Martin³³ at 61.8°C.(143.5°F.) for 30 minutes was not sufficient to secure negative phosphatase tests with all samples. Cream separated from milk pasteurized at 61.7°C.(143°F.) for 30 minutes was frequently positive for phosphatase. Pasteurization at 65.6°C.(150°F.) or higher for 30 minutes resulted in negative phosphatase tests. Most of samples collected in the field were negative.

The important observation was made by Barber and Frazier³⁴ that certain bacteria might render phosphatase-negative pasteurized cream posi-

33. Caulfield, Nelson, and Martin. 1940. J. Milk Tech. 3, 245-254.

34. Barber and Frazier. 1942. J. Dairy Sci. 25, 718.

tive for this substance after storage for 24 to 48 hours at 4°C.(39.2°F. to 10°C.(50°F.). This resulted from development of a Gram-positive sporeforming bacillus in both sterilized cream and skimmed milk. Barbe and Frazier believed that these observations explained the change in reaction of the phosphatase test from negative to positive on refrigerated pasteurized cream. Further information on this question is given on page 422.

Effect of Pasteurization on Coliform Bacteria in Cream. In a study of ice cream mixes, phosphatase was consistently more resistant to heat than some of the more resistant coliform bacteria (Nelson, Caulfield, and Martin³⁵). These authors wanted to know whether this relationship held for cream. They believed that such knowledge was necessary for proper evaluation of the significance of coliform bacteria in pasteurized cream. Their experiments indicated that phosphatase was more resistant than the coliform bacteria which were studied. This would seem to indicate that cream which had been sufficiently heated to destroy phosphatase would also have been heated sufficiently to destroy coliform bacteria. Presence of coliform bacteria in cream which was negative for phosphatase would therefore be considered to have been contaminated after pasteurization.

Phosphatase Test Applied to Butter. According to Scharer³⁰ application of the phosphatase test to butter requires change only in preparation of the sample. In the case of butter, the sample should be melted at a temperature below 37.8°C.(100°F.) so as to effect a complete separation of the water serum. One ml. of this water serum is then pipetted directly into 10 ml. of the buffer substrate. The rest of the procedure is the same as for milk and cream except that less lead acetate solution is required for precipitation. Phosphatase is concentrated in this water serum and consequently yields higher results than the melted butter.

Scharer found only slight phosphatase activity in butter made from "holder" pasteurized cream. Butter made from "flash" pasteurized cream exhibited considerable phosphatase activity. Some brands of commercially processed butters consistently showed no phosphatase activity, while others showed as many as 500 units even though they were stated to have been made from pasteurized cream.

Parker³⁶ quoted Shadwick's work on the application of the phosphatase test to creamery butter in which it was shown that only butter samples taken at the churn could provide basis for attesting thoroughness of cream pasteurization. This was confirmed in a report to the American Public Health Association.

Hammer and Olson³⁷ observed formation of phosphatase in butter to such an extent during the long holding period that consideration must be given this fact when applying the test to butter. Application of the phosphatase test to sour cream butter is subject to various factors which are not involved when it is used to test products made from sweet milk. Other

factors than technic must be recognized as causes of variations in results. Brown³⁸ found a concentration of the enzyme in butter during butter making. This fact may cause a positive phosphatase test for butter even though the cream gave a negative test. In 10 per cent of samples examined Brown noticed an increase in phosphatase value during storage at 15.6°C. (60°F.) for 10 days. This increase also occurred at temperatures considerably below 60°F. At -17.8°C. (0°F.) the phosphatase values remained constant. Production of phosphatase by bacteria in butter was not observed by Brown.

Various factors may influence the phosphatase test on flash pasteurized cream and butter made from it. When Wiley, Newman, and Whitehead³⁹ used the Kay and Graham "long" phosphatase test on pasteurized cream and on serum from butter made therefrom, the butter gave much higher values than the cream from which it had been made. Addition of salt, galactose, or sucrose produced no immediate effect on the test, but after several hours, phosphatase values were considerably higher. The authors believed that a small amount of phosphatase might escape destruction during very short heat treatments. No evidence was secured to indicate that phenolic substances were formed by bacteria. Wiley, Newman, and Whitehead concluded that the phosphatase test could not be used on butter to determine whether the cream from which it was made had been properly pasteurized.

Bacteria in Cream and Cream Ripening. Cream is usually pasteurized and ripened before churned. Conn⁴⁰ stated that cream ripening was more complex than the souring of milk; he was in doubt whether one species produced what is known as ripened cream. In 1890 he isolated over 50 different species which were grouped for study. From this work, he concluded that selected strains to be used in starters greatly influenced the flavor of the butter. Similar conclusions were reached by Emmerling and Schrodtt⁴¹ and De Vuyst,⁴² who worked with cultures obtained from Weigmann at Kiel. The latter investigator apparently thought that ripening was of lesser significance than some other bacteriologists believed. Conn⁴³ reported further results and announced discovery of *Achromobacter aromafaciens* (Bacillus No. 41) which was said to produce an aroma of high character and an excellent butter from cream ripened with it. This organism was isolated from a milk from Uruguay, which had become quite bitter. After showing that the organism produced flavor in butter characteristic of highest quality June butter, Conn studied the applicability of the organism in practical dairy work. Farrington and Russell⁴⁴ were unable to confirm Conn's work with Bacillus 41. Interest in the organism gradually diminished. Martiny⁴⁵ successfully used a culture of kephir for

ripening cream. The butter was pronounced to have a good flavor and keeping quality. Using commercial cultures, Vieth⁴⁶ could not always observe an unmistakable improvement, but believed that they might be of value in dairies where butter faults were present. Conn and Esten,⁴⁷ after a study of many bacteria from butter, believed that desirable flavor was connected with the presence of certain bacteria. Further work was reported by Hayward and McDonnell,⁴⁸ Eckles,⁴⁹ Heinemann and Class,⁵⁰ Mortensen,⁵¹ Laxa⁵² and others. Hammer and Baker,⁵³ who reported a comprehensive investigation on starters, observed that cream ripening was a symbiosis. While a single organism could be useful, the flavor was probably really due to a summation of the activities of several different species.

After considering the many papers which have been published on the question, one is forced to the conclusion that cream ripening has much to do with butter flavor. On this conclusion rests the use of starters which contain desirable bacteria.

Effect of Cream Ripening on *Eberthella typhosa* in Cream. The possible presence of *Eberthella typhosa* in cream stimulated considerable study to determine whether the organism could survive cream ripening. Northrup,⁵⁴ Potter,⁵⁵ and Krumwiede and Noble⁵⁶ could not observe pronounced action of the lactic acid-producing bacteria. The last-mentioned investigators believed that clean cream which soured slowly would be more dangerous if infected as an initial multiplication of organisms could occur. In artificially inoculated milk, Washburn⁵⁷ observed no decrease in numbers of *Eberthella typhosa* up to 20 days. Bruck⁵⁸ and Bolley and Field⁵⁹ also believed that cream ripening could not be relied upon to make infected cream safe. Confirmatory data were reported by Fraenkel and Kister,⁶⁰ Trillat and Fouassier,⁶¹ and March.⁶² The situation is not much different for *Salmonella* species (Kaiser⁶³). Health officials are therefore justified in demanding clean cream and clean water supplies. Further data on this subject are given in the chapter on "Fermented Milks."

Butter Cultures or Starters. Such agents are added to cream after pasteurization for improving flavor. They are the result of much research for special strains which can contribute the desired flavor and aroma. Conn,⁶⁴ at the Connecticut Agricultural Experiment Station, was one of the first

n America to study these agents. He early stated that certain forms of fermentation were desirable in butter making. Conn isolated the organism known as B41; this organism was believed to be especially desirable in butter. Farrington and Russell⁶⁵ could not agree with Conn after making a comprehensive study of this organism. This culture produced results which seemed to be in direct opposition to those Conn attributed to it. About this same time Hayward and McConnell⁶⁶ also studied several butter cultures. The results were not absolutely convincing. In fact these authors believed that more attention should be given to cleanliness and careful selection of milk rather than to rely on pasteurization and "butter cultures," a conclusion stated also by Farrington and Russell. Experience since these early days has not justified such conclusions. Despite the fact that some manufacturers of butter have doubted the value of butter cultures, their use seems to be vindicated in higher scores of butter and better keeping quality. It is possible to make more uniform butter with a better flavor.

Bacteriophage in Dairy Starters. Some difficulties in dairy starters have been attributed to presence of bacteriophage. Bacteria of value in producing good aroma and flavor in dairy products seem to be just as susceptible to attack by bacteriophage as other species. Sutton⁶⁷ isolated a bacteriophage from whey which lysed the streptococcus in a milk culture. This agent has been found also in cheese-starter cultures by Whitehead⁶⁸ and his colleagues. Their work is discussed more fully below in Chapter 9. In Whitehead and Hunter's⁶⁹ experiments, bacteriophage showed a strain specificity toward lactic acid-producing streptococci, but some races exist which attack as many as four different strains.

Flavor of Butter. Many factors are involved in flavor of butter and much work has been done on the relation of bacteria to flavor. When bacteriological studies were first made on butter, Conn suggested that a distinction be made between "aroma" and "flavor." Butter may have a natural flavor from the cream from which it is made. Sweet cream butter would have a different flavor than sour cream butter made from cream which had been pasteurized and inoculated with desirable bacteria. Much more is probably known about the bacteria which deteriorate butter than about those which give it desirable characteristics.

Keith⁷⁰ isolated a micrococcus that produced a butter flavor and aroma when grown on milk or cream; he designated it is *Micrococcus butyri-aroma-faciens*. Another organism, named *Bacterium aromaticus butyri*, was isolated by Sewerin.⁷¹ The aroma was produced in milk only when grown in symbiosis with lactic acid bacteria.

Hammer,⁷² using a culture of *Streptococcus citrovorus* for ripening the cream, produced a butter which had a higher score than other butter. It

was stated that while *Streptococcus lactis* (*Streptococcus lacticus*) played a very important role in cream ripening, it was the associated organisms which were really responsible for the desired flavor. A good starter is one in which a proper balance of these organisms is maintained. At Iowa State College, it was found that the sour cream butter scored higher than sweet cream butter, but after nine months' storage the sweet cream butter had a higher score. Butter made from sour cream pasteurized at 76.7°C. (170°F.) by the continuous process, was better than butter made from cream pasteurized at lower temperatures. Pasteurization at higher temperatures also shortened the keeping qualities. Other data have been published by Brown, Smith, and Ruehle,⁷³ Ruehle,⁷⁴ Dahlberg,⁷⁵ and others.

Separation of the qualities of butter known as flavor and aroma may be very close and perhaps artificial. Van Beynum⁷⁶ believed that aroma results from combined action of lactic acid-producing bacteria and special aroma-producing bacteria. Good aroma production was related to utilization of citrates. A special aroma-producing bacterium was named *Streptococcus lactis aromaticus* by Joshi and Ram Ayyar⁷⁷ while Bogdanov⁷⁸ attributed aroma production to *Streptococcus lactis cremoris*. Since this work was done much more has been learned about the actual substances which are involved. Van Niel, Kluyver, and Derx⁷⁹ showed that aroma of butter was due to acetyl methyl carbinol. Having determined this, numerous investigations were carried out to determine what role microorganisms might play in formation of this substance. Later investigations showed that it was diacetyl formed from acetyl methyl carbinol which is the real flavor-aroma agent in butter. This was a marked advance. Slat-ter⁸⁰ considered these substances to be most important and studied their formation in both salted and unsalted butters. Homologues of diacetyl in butter cultures were not observed by Prill, Fabricius, and Hammer.⁸¹ This indicated to them the importance of citric acid fermentation in flavor development. Not all who have worked on this problem agree as to the bacterial species which are involved. They are probably without doubt members of the lactic acid-producing group of bacteria, especially Streptococci. Wiley, Cox, and Whitehead⁸² found *Streptococcus cremoris* to be important. Betacocci were found to produce acetyl methyl carbinol and to destroy it quite rapidly. Its destruction becomes of as much importance in the butter industry as its formation. Its reduction to 2, 3-butylene glycol by *Aerobacillus polymyxa* has been reported by Stahly and Hammer.⁸³ Michaelian and Hammer⁸⁴ reported that oxidation of acetyl methyl carbinol was due to the activities of citric acid-fermenting Streptococci rather

than to direct chemical oxidation. These conclusions were amplified later by Michaelian, Hoecker, and Hammer,⁸⁵ Michaelian, Farmer, and Hammer,⁸⁶ and Hoecker and Hammer.⁸⁷ The last-mentioned investigators observed that some microorganisms favored formation of these agents while others caused a decrease in their content. Butter culture containing *Streptococcus diacetylactis* and *Streptococcus citrophilus* when added to cream caused an increase of flavor agents, while *Streptococcus citrovorus* and *Streptococcus paracitrovorus* often caused decreases. Importance of certain species of bacteria to good flavor and aroma production was well indicated.

Conditions under which cream is held apparently may have much influence on aroma production by these chemical substances. Oxygen has been shown to be important by several investigations. Virtanen, Mansikkala, and Tikka⁸⁸ and Virtanen⁸⁹ secured no acetyl methyl carbinol in thick layers of milk but large amounts in thin layers. Bubbling air through the cultures caused marked increases in the amount formed in experiments of Brewer *et al.*⁹⁰

DETERIORATION OF BUTTER

Deterioration, in general, may be caused by various agents among which the microorganisms play a large part. Those which exhibit some marked characteristic, such as formation of a pigment or a special excretory product, have been especially troublesome. Abnormalities in butter resulting from activities of microorganisms may vary from slight imperfections to those which are so serious that they must be investigated. *Pseudomonas fluorescens* has been found by various investigators as the cause of spoilage (Prikrýl⁹¹ and Sadler, Vollum, and Cameron⁹²). Large numbers of proteolytic bacteria, according to Flake and Parfitt,⁹³ are objectionable. They also believed that lipolytic bacteria might cause deterioration. Jacobsen⁹⁴ observed no relation of flavor deterioration to members of these groups.

Fishy Flavor in Butter. This is one of the most easily recognized abnormal flavors encountered in butter. Considerable work has been done on its microbiology. O'Callaghan⁹⁵ reported that *Oidium lactis* caused it. Inoculation experiments proved it, since controls did not develop the fishy flavor. Pasteurization was found to kill the organism and allow the development of good flavor, 75.6°C. (168°F.) being sufficient. Cleanliness in and about the dairy was said to be necessary to prevent contamination of the milk. Rogers,⁹⁶ however, could not confirm O'Callaghan's statement that a fishy flavor could be produced by inoculation with *Oidium lactis*. A

biological study was made of farms, but no condition was found in the pastures and on the farms furnishing milk from which fishy butter was made which did not exist on some of the farms producing normal butter. This applied to the water supply as well as the flora of the pastures. These results seemed to exclude the possibility of any direct connection between the feed of the cows and the presence of the fishy flavor in the butter. Fishiness could not be produced in butter made under winter conditions by any combination of circumstances. Bacteriologically, the only peculiarity of the cream from the farms where the fishy flavor was developed was the presence of very active lactic acid bacteria. In all cases in which the records were complete it was found that those experimental butters which became fishy were made from high-acid cream. Fishy butter was made from cream acidified with lactic and acetic acids. However, cream with high acidity does not uniformly develop fishiness.

It was apparent that acidity, although having a determining influence on the fishy flavor, was not its sole cause. The effect of over-working butter was next investigated, and it was observed that fishiness occurred in a combination of high acidity and over-working. Further experiments in this line showed that over-working improved rather than impaired the flavor of the unripened cream butter. In the opinion of Rogers, fishy flavor was caused by a slow, spontaneous, chemical change to which acid is essential and which is favored by the presence of small amounts of oxygen. Rogers believed that fishy flavor could be prevented with certainty by making butter from pasteurized sweet cream. Butter made from pasteurized sweet cream with a starter but without ripening seldom if ever becomes fishy. Reakes, Cuddie, and Reid⁹⁷ isolated pure cultures of organisms from butter having a fishy flavor but failed to produce the effect experimentally. Butters of fishy flavor were found to contain a high percentage of acid, and it is, therefore, thought that a high acidity may be a contributing factor though not the direct cause of the trouble. According to Sommer and Schmidt⁹⁸ the conditions favoring the causation of fishiness in butter were high acidity in the cream, high salt content of the butter, over-working of the butter, and the presence of iron and copper salts. The real cause of the presence of this fishy taste rested on the formation of trimethylamine from lecithin. Johnstone⁹⁹ stated that the lecithin combined with air to form cholin which then decomposed to form, among other things, trimethylamine. Dyer¹⁰⁰ believed that fishy flavor of cold-stored butter was not due to oxidation of fat. Fishiness in butter was attributed by Davies¹⁰¹ to oxidation of the choline residue of lecithin to yield trimethylamine.

Yeasty Flavor. This spoilage is characterized by the fact that yeasts have not been entirely to blame for the deterioration. Some of the trouble, according to Rosengren,¹⁰² originated with the starter which was allowed to over-ripen. Rosengren studied one starter which produced yeasty butter, finding that *Lactobacillus lactis acidi* favored the development of the yeast. When the starter was stored below 20°C. (68°F.) the yeast grew abundantly. Many lactose-fermenting yeasts have been reported which are able to proliferate in cream. Among the better known are *Torula cremoris* and *Torula sphaerica*, isolated by Hammer.

Turnip Taste. This flavor has been attributed to the presence of turnips in the diet of the cow as well as to the growth of certain bacteria in the butter. Weigmann¹⁰³ found that the milk from cows fed on turnips had a peculiar odor and flavor. Apparently some volatile product from the turnips gets into the body fluids of the cow and thus affects the milk. This fault may be corrected by warming or aerating the milk. Besides this, certain organisms, as coli organisms, *Actinomyces odorifer*, *Penicillium brevicaulis*, and lactic-acid bacteria, which are found in the feces of cows fed on beets or turnips, also produce the turnip flavor and aroma in butter made from milk or cream in which they are present. The turnip flavor of butter may be due to both of these causes together. Butter may have the turnip flavor and aroma, however, even when no turnips are fed, as coli bacteria causing the taste are found also on oats, barley, corn, rape, and other feed stuffs. Pasteurizing the milk, with subsequent aeration, is recommended as a means of preventing the development of the turnip flavor in butter. This work was continued by Weigmann and Wolff.¹⁰⁴

Cheesy Flavor. This defect was shown by Herreid, Macy, and Combs¹⁰⁵ to be caused by microorganisms in the raw cream. While pure cultures of the several bacteria would not always produce this off-flavor, they usually did when used together in mixed cultures. Gram-negative, rod types of bacteria predominated in the mixed and pure cultures capable of producing the Cheddar cheese type flavor. This flavor in cream or unsalted butter occurred most typically at temperatures of 10°C. (50°F.) or below. Creamery water supplies were sometimes contaminated with bacteria capable of producing the off-flavor, and sterile cream butter may be infected through contact with such water. The plasma of cream contained the substrates necessary for the development of the causative flora producing the cheesy flavors and aromas.

Metallic Taste. This term depicts sufficiently well the flavor indicated. Ruehle¹⁰⁶ reported the appearance of metallic flavor in butter from cream to which iron or copper lactate had been added and also by the use of cream containing organisms of the *Bacillus subtilis* group. He believed that the bacteria produced the flavor by decomposition of the casein. On account of the fact that this organism and its close relatives are spore-formers, it will survive pasteurization. Consequently the presence of the organism in milk from which butter will be made is of more significance than its presence in milk which will be used in a short time. Houston¹⁰⁷ reported that *Bacillus subtilis* caused bitter butter. It is very probable that the same off-flavor may have been described in different ways by investigators.

Musty Flavor. Musty flavor was attributed by Randell¹⁰⁸ to an unnamed member of the genus *Achromobacter* as the causal organism. The organisms may have originated in the creamery from unsterilized equipment. Musty odors are often related to development of molds but bacteria have been found to be just as important, if not more so.

Rancidity of Butter. This is a term which includes many abnormalities of edible fats and oils. Investigation of rancidity from a scientific viewpoint is rendered more difficult, according to Lea,¹⁰⁹ by the fact that

ultimate standards to which all data must be referred are based on taste and smell, the most elusive and least clearly defined of the five senses. He further pointed out that the term "rancidity" has been employed in the past, either in the general sense to indicate deterioration in odor and flavor without attempt to specify the cause, or as applying to some particular type of spoilage. In the latter case, it has usually been applied to hydrolytic changes produced in butter and similar fats by action of enzymes or microorganisms while "tallowiness" has been used to denote oxidation. The deterioration is quite often characterized by a butyric acid odor. Guthrie^{109a} reviewed the literature and reached the conclusion that rancidity as defined by butter judges, is rarely found. He believed that many alterations in flavor were explained as rancidity when better descriptions could have been given. Studies on butter rancidity were made quite early. Amthor¹¹⁰ believed that rancidity was due to bacteria which produce alcohol from lactose. Simultaneous cleavage of the fats occurs which yields acids for ester formation. Another claimed that rancidity, in some cases, was due to intensive development of "bouquet." Orla-Jensen¹¹¹ believed that the changes which took place in rancid butter involved the fat mainly. These changes were said to be oxidative and hydrolytic. While Orla-Jensen considered the various causes of rancidity, he gave special attention to the bacteria which might be involved. This portion of the paper may be reviewed at greater length.

It was shown that several forms of microorganisms commonly occurring in butter were capable of decomposing the butter, with the formation of volatile fatty acid and esters. This, Orla-Jensen believed, was sufficient proof that the rancidity of butter may be due to microorganisms, and that the hypothesis of the action of a milk enzyme is very improbable. It was thought very possible, however, that the microorganisms effect the cleavage of the fat by means of an enzyme (steapsin) which they form. Orla-Jensen added to filtered and sterilized butter a quantity of an old milk culture of the organisms to be tested which had been passed through a Chamberland filter. Samples of butter were treated in this way with cultures of *Pseudomonas fluorescens* (*Bacillus fluorescens liquefaciens*) and of *Oidium lactis*. These experiments showed that the acid number increased, i.e., that the rancidity progressed, and it was concluded that this was due to enzymes (steapsin).

The microorganisms which, under ordinary conditions, caused rancidity are *Oidium lactis*, *Cladosporium butyri*, *Pseudomonas fluorescens* (*Bacillus fluorescens liquefaciens*) and occasionally *Serratia marcescens* (*Bacillus prodigiosus*) also. All of these cleave the butter-fat. Some of these organisms are introduced into butter by contaminated water.

Volatility of acids formed in rancid butter is not necessarily related to degree of rancidity. Fouts¹¹² observed considerable variation in total fatty acids in sterile cream inoculated with *Oospora lactis*, *Mycotorula lipolytica*, *Pseudomonas fluorescens*, and *Achromobacter lipolyticum*. Mold growth in butter causes both an acid-oxidative rancidity and a ketonic rancidity, according to Davies.^{112a} The former is due to molds containing lipases

and being able to metabolize glycerol; the latter, on the other hand, was said to be due to molds developing on the surface of the butter. Microorganisms causing rancidity in dairy products seem to be regular contaminants. With proper enrichment procedures, Garrison and Hammer^{112b} observed fluorescent bacteria to be widely distributed in milk, cream, ice cream, and butter and also in water from a dairy barn and its surroundings. Selected cultures produced off-flavors in butter. Salt had variable effects on the strains.

Putrid Butter. Eckles¹¹³ examined samples of butter having a strong disagreeable taste and a putrid odor. Three kinds of bacteria were isolated which produced very bad effects on the milk and were thought to be the cause of the putrid butter. The principal difference between the spoiled butter and the sweet butter was a large number of gelatin liquefiers in the spoiled butter. Eckles stated that the milk was contaminated in some manner before it was delivered to the creamery. Better sanitation stopped the trouble.

Pseudomonas fluorescens was found to be the cause of putrefactive flavor in pasteurized creamery butter by Shutt.¹¹⁴ The organism came from water. Cultures of this organism in ordinary media possess a strong odor. Filippini¹¹⁵ also stated that the fluorescent bacteria were active agents in butter spoilage. Whether they produce true rancidity may be questioned.

Surface taint has caused some trouble in the butter industry and has been related to microorganisms by Derby and Hammer¹¹⁶ who found many more bacteria on the surface of butter than in the interior. While the defect was not produced by inoculating a normal product with tainted butter, it was reproduced by inoculating pasteurized cream with tainted butter and churning the cream. *Achromobacter putrefaciens* was believed to be the causal organism and is probably identical with *Pseudomonas fluorescens*. Some years later Claydon and Hammer¹¹⁷ isolated the organism from putrid butter by means of the Burri film-culture method. It was about the only organism obtained which reproduced the defect on inoculation. Forty-one strains of this organism studied by Wolochow *et al.*¹¹⁹ were observed to be quite pleomorphic and variable in activity. The organism was strongly proteolytic.

Later work by Long and Hammer¹¹⁸ indicated that *Pseudomonas putrefaciens* syn. *Achromobacter putrefaciens* was commonly present in certain dairy products. It was isolated from raw, sweet milk and cream and from normal and putrid salted butter but not from sour cream or highly ripened, unsalted butter, where the sensitivity of the organism to acid may have resulted in its destruction. It was obtained from a sample of moist soil but not from three samples of dry soil; from stream, lake, and roadside water collected in various states; from creamery water supplies; and from the floors and sewers in dairy plants, particularly from sites that tended to remain moist.

In studies of dairy equipment, *Pseudomonas putrefaciens* was obtained from parts of a butter printer in a plant that was having difficulty with putrid butter. This printer had probably been infected from the butter since the butter contained the organism before printing. The organism was also obtained from three of four churns that were examined by culturing material from around bolt heads, from between staves, from the junction of staves and ends, etc. These churns were in plants that were encountering putrid butter. Finally, it was obtained from the lining of a leaky milk vat immediately after the vat was taken out of service.

Wolochow, Thornton, and Hood¹¹⁹ were unable to identify the precursor of surface-taint substance. The strain of *Pseudomonas putrefaciens* which they investigated grew at 20°C.(35.6°F.) and at 32°C.(89.6°F.) but not at 37°C.(98.6°F.). It did not survive 54.4°C.(130°F.) for 10 minutes. When grown in skim milk it produced a typical putrid odor. There was some suggestion that outbreaks of surface taint in butter followed institution of high-temperature heat treatment of churning cream. *Pseudomonas putrefaciens* is widely distributed in Alberta (Canada) waters and is found also in the United States and Australia. Later work by Dunkley, Hunter, Thornton, and Hood (1942) indicated the substance causing the trouble was related chemically to isovalerianic acid.

The fluorescent bacteria have also been related to butter defects as they have to defects in other foods. Garrison and Hammer¹²⁰ observed that selected cultures of these bacteria produced various off-flavors in milk and cream held for 18 days at 5°C.(41°F.). Rancidity was not detected although lipolytic cultures were included in those which were used. While various off-flavors were observed, putrid and rancid butter were especially common. The fluorescent bacteria were found to be widely disseminated in water and in various dairy products.

Skunk-Like Odor in Butter. This is one of the unusual odor defects observed in butter. Claydon and Hammer¹²¹ observed development of a skunk-like odor in three samples of butter held at 21°C.(69.8°F.) to test its keeping quality. When the defective butter was inoculated into pasteurized sweet cream and the cream churned, the defect was reproduced. The causative organism, *Pseudomonas mephitica*, was isolated and described. On inoculating the pasteurized cream used for churning, the defect developed in unsalted butter made from cream having pH values from 5 to 7.5. Salt had an inhibitory effect on the production of the defect but thorough working of the salted butter was necessary to prevent its appearance. The skunk-like odor was produced in unsalted butter by inoculating small amounts of culture into water used to wash the butter.

Microbial Discoloration of Butter. Several bacterial species have been isolated which impart abnormal colors to butter. Olson and Hammer¹²² mentioned developments of pink color in butter for which no specific microorganisms could be isolated. Consequently they suggested that the deteri-

121. Claydon and Hammer. 1939. *J. Bact.* 37, 251-258.

122. Olson and Hammer. 1933. *Iowa State Col. J. Sci.* 7, 487-491.

oration might be chemical in nature. A violet color in butter was attributed by Deshauses and Novel¹²³ to a bacterium named *Bacillus janthinus* var. *butyricus*. A similar deterioration was reported by Morgan,¹²⁴ who reported the cause to be *Chromobacterium violaceum*. A pink color was attributed to *Rhodococcus rosaceus*, a green color to *Pseudomonas fluorescens*, and a bright orange color to an unidentified rod-shaped organism.

An organism causing a dark discoloration in butter containing .38 to .55 per cent salt was isolated by Hiscox.¹²⁵ At 15°C.(59°F.) a brownish color developed and diffused through the medium. At lower temperatures this was mixed with a blue-black pigment insoluble in water, brine, chloroform, ether, ethyl, and methyl alcohol, butterfat, and dilute sulphuric and acetic acids, but soluble in formalin. During growth of the organism the blue-black pigment was excreted from the cells and deposited as irregular aggregates of platelets varying considerably in size and shape. The nature of the source of the nitrogen influenced the development of this pigment, proteose appearing to be inhibitory. The brown pigment produced at higher temperatures may probably be attributed to the action of ammonia produced by the organism.

The organism, a rod with rounded ends, nonsporing, actively motile, and Gram negative, was regarded as a species of *Pseudomonas*. In litmus milk it produced alkalinity with bleaching and digestion at all temperatures up to 30°C.(86°F.). At 1 to 3°C.(33.8 to 37.4°F.) the action was very slow, a dark ring developing to a depth of about one-half inch. No growth was obtained on standard agar, yeast-dextrose agar, beerwort agar, bean agar, and potato. The first two media became satisfactory for growth with the addition of one-half per cent NaCl. With five per cent NaCl growth became very scanty. The causal organism of a blackening of butter was identified as *Pseudomonas nigrifaciens* by White.¹²⁶ This halophilic bacterium produced reddish-brown spots on the surface of the prints. Plant sanitation and use of enough salt to result in seven per cent in the serum was recommended. *Pseudomonas nigrifaciens* does not survive minimum pasteurization temperatures of 76.7°C.(170°F.) for 10 minutes used in Canadian creameries.

Jamieson's¹²⁷ "Butter-Shake" Method for Identification of Bacteria Which Deteriorate Butter. This method was proposed for determining whether bacteria were the causative agents in butter deterioration. Jamieson referred to his technic as the "Butter-Shake Method." It was devised principally for testing the effects of pure cultures on butter but was also used for determining whether waters were suitable for use in creameries. Butter of clean flavor and low microanalytical count is melted to a creamy consistency and poured aseptically in 20-ml. amounts into special wide-mouthed, screw-capped glass vials four inches high and one inch in diameter, giving a 45-ml. capacity. These are then chilled quickly and held at freezing temperature until used. The butter used in this test should be prepared under exacting conditions. The required amount may be easily made in a bacteriological laboratory from whole milk and refrigerated cream using sterile glass churns, water, salt, and other materials and utensils. The butter in

the vials may be inoculated with the pure culture by use of a sterile graduated pipette. The butter may be left in the solid form until all vials have been inoculated and labeled, after which it may be melted at a temperature of not over 40°C. (104°F.). Higher temperatures may produce undesirable textures. Thorough distribution of the inoculum throughout the butter is attained by vigorous agitation for 20 minutes on a shaker set to hold as many vials as are required for any test. The butter cultures with the vial caps loosened one-half turn are then incubated at the desired temperature for the time most favorable for development of off-flavors. For removal of samples for flavor determination, strips of 20-gauge stainless steel, five inches by five-eighths inch, and preferably shaped longitudinally to a half-round are effectively used.

Microbiology of Butter. On account of the raw materials, the methods of manufacture, and the fact that bacteria are added in large numbers to the cream before churning, the microbiology of butter has different import from that of other dairy products. This is one of the few dairy products, the bacterial plate count of which has not been attempted as an index of manufacturing conditions. The microbiology of butter has been studied by many investigators. Of these, Sawyer, Rahn, and Farrand,¹²⁸ and Fettick¹²⁹ reported rather large numbers of bacteria. Sawyer, Rahn, and Farrand could not find a characteristic flora, but believed that variable numbers of bacteria in butter were probably due to many different factors, such as bacteria in the cream, amount of salting, temperature of storage, etc.. Torr ¹³⁰ reported a bacterial content of fresh butter of from 36,000 to 7,000,000. Maximum numbers of bacteria were attained in from 13 to 14 days, after which there was a slow decline in numbers.

Rosenau, Frost, and Bryant¹³¹ studied 25 samples of butter, scoring from 80 to 98, representing the market supply of Boston. The average number of bacteria per gram was determined by emulsifying the butter in warm water. The average number for the 25 samples was 5,700,000 per gram; the lowest number was 8,600 and the highest 41,000,000. There was no particular relation between the number of bacteria and any other constituent determined, such as salt, reaction, moisture, etc. The number of bacteria diminished markedly with age; in one sample 85.8 per cent in two weeks, in another 93.7 per cent in four weeks, and in another 95.6 per cent in six weeks. It was suggested that the number of bacteria may, therefore, be used as an index of the age of the butter. *Escherichia coli* was found in only six of the 25 samples, and then only in small numbers. It seems that *Escherichia coli* soon dies out in butter. Streptococci were found in 14 samples, but no special relation between their presence and virulence as tested upon guinea pigs could be made out. *Clostridium welchii* were not found in any of the samples. Tubercle bacilli were demonstrated in two of 21 samples tested for these organisms and from butter of apparently first quality. Pasteurization of cream intended for butter is recommended. Brown, Smith, and Ruehle¹³² also reported relatively high numbers of bacteria in butter over a year old. After 275 days' storage,

lactic acid bacteria were noticeable, and in one case, were found after 462 days' storage.

Much study has been given to the relation of salt to butter quality. From two to four per cent of salt is added to butter which, when dissolved in the 15 per cent of water found in butter, gives a brine of about 30 per cent concentration. Fettick,¹²⁹ after inoculating pure cultures into sterile butter, found that several molds, *Pseudomonas fluorescens*, and lactic acid bacteria grew in three per cent of salt. *Escherichia coli*, *Bacillus subtilis*, *Aerobacter aerogenes*, and some torulae multiplied in six per cent concentration. Fettick concluded that three per cent of salt should be used in butter. Rahn, Brown, and Smith¹³³ found that salted butter kept better than unsalted, and Thom and Shaw¹³⁴ reported that two and one-half to three per cent of salt was necessary to repress mold growth. Much larger amounts of salt, according to Giltner and Baker,¹³⁵ do not restrict development of all microorganisms. Some bacteria were able to withstand 20 per cent of salt. Streptococci were found to be sensitive to salt, while staphylococci and micrococci were not. The greater part of the yeasts and torulae in butter cannot withstand as much salt as the cocci. Eight per cent of salt was believed to limit the physiological activities of most bacteria. Continued cultivation of some organisms on salt agar increased the salt tolerance. Pont¹³⁶ reported an ill-defined relation between microorganism content of butter and market gradings. Changes in flavor under storage conditions seemed to have little relation to microbial activity.

Reports of numbers of bacteria in butter do not tell much unless the manner of their distribution is considered. Rahn and Boysen¹³⁷ did this when they related the number of bacteria to moisture dispersion. Moisture in butter is distributed as droplets varying in size between one μ to over 100 μ in diameter. Most of them are less than five μ in diameter. Between 10 and 18 billion droplets per gram were found in butter. The largest number of bacteria in butter ever recorded in literature is 57 billion per gram. Comparison of this figure with the number of droplets would indicate that there are not enough bacteria to supply each droplet with one cell. Even with the most uniform distribution, only one droplet in 200 could contain a bacterium; the remaining 199 droplets would be devoid of bacteria. This statement is based on a much higher number of bacteria than would usually be found in butter. Rahn and Boysen¹³⁷ and Rahn¹³⁸ found the amount of infected moisture in butter to vary from 4.8 to 41 per cent of the total moisture in the samples. Lactic acid formation in butter proceeds much more slowly than in its buttermilk, and final acidity is also much lower, proving that actually part of the moisture in butter must be sterile, but the acidity that rises above the computed concentration indicates some diffusion of acids. In butter, with 100,000 bacteria per

138. Rahn. 1928. Sci. Mo. 27, 206-211.

gram, 88 per cent of the moisture is sterile; with 10,000 bacteria, 99 per cent is sterile; and with 1,000 bacteria, 99.9 per cent is sterile. This last butter cannot be attacked noticeably by bacteria. These deductions do not apply to molds, which can force their way from one droplet to another through the surrounding walls of fat.

Washing of butter, according to Rahn and Boysen, resulted in an uneven distribution of food and bacteria, the smallest droplets containing undiluted buttermilk but very few bacteria, the largest droplets containing most bacteria but practically nothing but the wash water of the butter. This accounts for the better keeping quality of washed butter. Working of the butter breaks the moisture into smaller droplets. The practical aspects of this were investigated by Long and Hammer.¹³⁹ In experimental unsalted butter, made from pasteurized cream inoculated with pure cultures of bacteria, growth of bacteria at 21°C. (69.8°F.) and at 5°C. (41°F.) was most rapid in underworked butter. Distribution of organisms in fresh butter was regular; after holding at 21 or 5°C., long enough to allow considerable growth, the distribution in the underworked and moderately worked butter was usually irregular, that in thoroughly worked butter was more regular. When the butter contained an organism capable of producing a flavor defect, the period required for its appearance at 21 or 5°C. increased as the working was increased. The pH values of the serum of butter made with butter culture decreased more rapidly at 21°C. and reached lower final values in underworked than in thoroughly worked butter, while moderately worked butter gave intermediate values. Acid numbers on the fat of butter containing a lipolytic organism and held at 21°C. indicated that underworking resulted in higher values than through working.

Bacteria in butter come from many different sources. Olson and Hammer¹⁴⁰ found the churn to be a fertile source. Agar disk counts on the internal surface of many churns varied. Churns which were thoroughly cleaned with hot water contained few living bacteria. Many bacteria in butter come from the air. Protection of churns from such contamination increased the keeping quality of butter.

Coliform Bacteria in Butter. Coliform bacteria may at times be present in milk and cream. They may reach butter from contaminated cream or they may be present in wash water. Hammer and Yale¹⁴¹ found them to contribute off-flavors. Salting seemed to inhibit them for they grew well in unsalted butter. *Escherichia* species did not produce off-flavors but *Aerobacter* species did in both salted and unsalted butter. The same observations were made by Rice¹⁴² on Australian butter. French butter, according to Dienert¹⁴³ also contained members of this group. He found their concentration to be inversely proportional to the acidity. In view of the sanitary significance of these bacteria Dienert believed they might indicate unwholesome conditions of manufacture and handling.

Survival of Pathogenic Bacteria in Butter. This subject has been discussed in the author's *Food-Borne Infections and Intoxications*. Just one report of results will be mentioned here since it concerns more common bacteria which might get into butter. Berry¹⁴⁴ inoculated butter with a broth culture of each organism, both on the surface and throughout the mass. A specially modified MacConkey's medium was employed, and the number of pathogens was counted in poured plates. *Streptococcus scarlatinae* was grown on poured blood agar plates. The experiments indicated a rapid decrease in numbers during the first few days. The periods of maximum survival for the various organisms under observation were *Salmonella enteritidis*, 228 days; *Salmonella schottmülleri*, 212 days; *Salmonella paratyphi* A, 117 days; *Eberthella typhosa*—Mississippi, 22 days; *Eberthella typhosa*—Talledega, 110 days; *Salmonella suipestifer*, 49 days; *Shigella dysenteriae*, 18 days; *Streptococcus scarlatinae*, 17 days. These results indicate that butter must be regarded as a potential source of infection.

Carbonated Butter. Proposals have been made in the past that carbonation of various foods would bestow on them various benefits. None of these claims seems to have been confirmed. Hunziker¹⁴⁵ disclaimed them and stated that carbonated butter is subject to all the ailments to which normal butter is subject, if made from unpasteurized cream. He denied that carbonation would preserve vitamins or that it protected vitamins; that harmful bacteria would be destroyed; that it is free from flavor defects; or that carbonation improves the flavor. This position was also taken by the Iowa Agricultural Experiment Station.¹⁴⁶ Results of experiments by Prucha, Brannon, and Ruehe¹⁴⁷ in general were in agreement. Carbonation of sweet cream at first caused a slight reduction of bacteria and retarded development of acidity. It did not prevent bacterial growth which later occurred at practically the same rate as in uncarbonated cream, though the types of bacteria were somewhat different. Quality of butter was not improved by churning in presence of carbon dioxide. Carbonation of dairy products was without effect. It influenced keeping quality in some cases but to a slight extent.

MICROBIOLOGICAL EXAMINATION OF BUTTER

The methods which have been developed for microbiological examination of butter are quite like those which have been devised for other foods. Various organizations have proposed methods among which may be mentioned the American Dairy Science Association, the American Public Health Association, and the American Butter Institute.¹⁴⁸ All of these organizations have had committees which have studied procedures. Besides these reports there are results of studies by individuals, such as those of

Parfitt¹⁴⁹ and Moir and Russell.¹⁵⁰ The purposes for making laboratory examinations usually determine the type of examinations made. Moir and Russell used with satisfaction a microplate method for bacterial analysis of butter. It was believed to be superior to older methods because time was saved and the results were just as satisfactory.

British Standard Methods for Microbiological Examination of Butter.¹⁵¹ This is a concise method of analysis; it is quoted as it appears in the original publication.

A. GENERAL.

5

Method of Sampling.

“1. It is essential that a sample properly representative of the bulk shall be taken. After determining the results of samples composed of 3, 6 and 12 cores, the Committee has concluded that a sample composed of 3 cores taken at appropriate points from a package of butter (reaching to the centre and including the surface portion) is reasonably representative of the bulk. The total sample shall be not less than 2 oz. (See also B.S. 809.) The sample shall be transferred to a suitable sterile container.

“As the micro-organisms present at the surface of the package are often of importance, the surface layer may be examined separately. For this purpose the surface shall be removed to a depth of $\frac{1}{4}$ in. by means of a sterile scraper and tested in the same way as the bulk sample.

“All analyses shall be carried out within six hours of sampling or the temperature of the sample shall be reduced to 40°F. and the examination carried out within 48 hours.

Treatment of Sample.

“2. For the purpose of examination the sample shall be quickly melted at a temperature not exceeding 45°C. by immersing the bottle for a short time in a water bath at 50°C. thoroughly mixed by shaking 50 times with an excursion of one foot in about one minute and a quantity of 10 ml. transferred without delay to 90 ml. of diluent in a suitable bottle of approximately 200 ml. capacity, using pipettes and diluent at 45°C. This will give a dilution of 1 in 10.

“The diluent and butter shall be shaken together 25 times with an excursion of 1 foot in about one minute, in order to obtain a homogeneous suspension.

“Subsequent dilution shall be made by transferring 1 ml. quantities of dilutions to 9 ml. quantities of diluent in test tubes at room temperature.

Apparatus.

- “3. (a) Test Tubes (152 mm. x 16 mm., B.S. 625).
(b) Pipettes (B.S. 700).
(c) Petri dishes (B.S. 611).
(d) Stopped 200 ml. bottles.

Diluent.

“4. Dilutions of the butter under test are made in quarter-strength Ringer's Solution, containing 0.1 per cent agar to stabilize the emulsion.

<i>Ringer's Solution.</i> (full strength)	Sodium chloride	9.0 g.
	Potassium chloride	0.42 g.
	Calcium chloride	0.24 g.
	Sodium bicarbonate	0.2 g.
	Glass distilled water.....	1 000 ml.

149. Parfitt. 1934. Amer. J. Pub. Health 24, 303-308.
150. Moir and Russell. 1939. J. Dairy Sci. 10, 310-325.
151. Reprinted by permission from British Standards No. 895—1940, *British Standard Methods for the Microbiological Examination of Butter*. April, 1940. (Official copies may be obtained from the American Standards Association, 29 West Thirty-Ninth St., New York, N. Y.)

"Dissolve the constituents in glass distilled water, or other distilled water free from toxic metals.

"Dilute the full strength Ringer's Solution 4 times with glass distilled water, add 0.1 per cent washed fibre agar, heat to dissolve, sterilise by autoclaving for 15 min. at 120°C. and fill out 9 ml. quantities into test tubes (152 mm. x 19 mm., B.S. 625).

Plating and Counting.

"5. (a) *Dilutions of Butter to be examined.*—It will be appreciated that it is not possible to state what numbers or levels of dilutions shall be plated, as the number of organisms varies greatly from butter to butter. For routine purposes, dilutions need seldom exceed 1/10 000, as all counts greater than 5 000 000 indicate heavy contamination

"An indication of the dilutions generally suitable is given with each medium.

"(b) *Pouring the Plates.*—Within 10 minutes of preparing the dilutions transfer 1 ml. quantities of each dilution to the plates; add 10 ml. of the medium, cooled to between 45° and 48°C., and mix with the dilution by rotary movements in a horizontal plane. After pouring the plates as quickly as possible with the minimum of exposure to light, cover with a black cloth and allow to harden for 30-60 minutes.

"(c) *Incubation.*—Invert the plates and transfer to an incubator which shall maintain the desired temperature within the range $\pm 1^\circ\text{C}$. Anhydric incubators are not recommended.

"(d) *Counting.*—After incubation for the specified time, count the colonies with the aid of a specially constructed box permitting the examination of the plates by combined reflected and transmitted artificial light against a dark background. A lens of 4 in. focal length magnifying $2\frac{1}{2}$ diameters shall be used.¹⁵²

"To facilitate counting, the plate may be divided into quarters by lightly ruling with a grease pencil.

"Mark the colonies with ink or grease pencil without using the lens; then scan the plate with the lens and complete marking. Record the colonies as they are marked by means of a tally counter.

"All plates considered to have colony numbers between 30 and 500 shall be counted.

"The count shall be computed from the number of colonies on that countable plate which contains the highest concentration of butter.

B. MEDIA FOR THE DIFFERENTIAL ENUMERATION OF VARIOUS MICRO-ORGANISMS IN BUTTER.

"The media described below shall be used as required for estimations of the numbers of organisms of different types which may be desirable for general or special purposes.

Yeasts and Moulds.

"1. The yeast and mould count may be regarded as an index of the care used in preparation of the butter.

"The work of the Committee has shown that there is no statistically significant difference between the counts obtained on:—

- | | |
|------------------------|---|
| (i) Beerwort agar | } the pH value being 3.5, the plates being counted after incubation for 3 days at 25°C. |
| (ii) Malt extract agar | |
| (iii) Dextrose agar | |
| (iv) Yeast salt agar | |

"In order to make it possible for workers in all countries to make use of those constituents of media which are most easily obtained the composition of the above media is given below:—

(a) *Preparation of Media.*

(i) *Diluted Beerwort.*

¹⁵² Counting devices are recommended which involve combined reflected and transmitted artificial light against a dark background. Such devices are described by Wilson in Med. Res. Council Special Rpt. Series, No. 206, p. 102; Standard Methods for the Examination of Dairy Products, Eighth Edition, 1941, also describes one.

"Heat unhopped wort as received from the brewery to 100°C. for 1 hour, filter through pulp, allow to cool to 20°C. and add an equal volume of tap water. After thorough mixing, fill out the medium into flasks and sterilise by steaming for half hour at 100°C. on each of three successive days.

(ii) *Malt Extract.*

"Mix 100 g. of malt of high diastatic value with 1 000 ml. of tap water and hold at 50° to 55°C. until no colour reaction is obtained with iodine. Then raise the temperature to 100°C., filter the mixture and sterilise by steaming at 100°C. for 30 min. on each of three successive days. Alternatively, a 3 per cent solution of commercial malt extract (approximately 80 per cent of malt solids), free from preservatives, shall be used.

(iii) *Dextrose Broth.*

Dextrose.....	20 g.
Peptone ¹⁵³	10 g.
Commercial beef extract or yeast autolysate ¹⁵⁴	5 g.
Tap water	1 000 ml.

"Dissolve the constituents in hot tap water and raise to 100°C. Filter and make up the volume to 1 000 ml.

Experiments have shown that the type of peptone used in media for yeast and mould counts does not appear to influence the result.

(iv) *Yeast Salt Broth.*

Ammonium nitrate	1 g.
Ammonium sulphate	1 g.
Dipotassium hydrogen phosphate.....	4 g.
Potassium dihydrogen phosphate.....	2 g.
Sodium chloride	1 g.
Dextrose.....	1 g.
Commercial yeast autolysate.....	1 g.
Tap water	1 000 ml.

"Dissolve the constituents in hot tap water and raise to 100°C. Make up the volume to 1 000 ml.

"(b) *Addition of Agar.*—Add 20 g. of washed fibre agar per 1 000 ml. of medium, dissolve by raising to 100°C., and sterilise by autoclaving at 120°C. for 15 minutes.

"(c) *Adjustment of Media.*—*Media i, ii and iii.*—Add citric acid (10 per cent solution, previously autoclaved as in (b), aseptically to the medium at 90°-100°C. to bring the pH value to approximately 3.5, using bromphenol blue as an external indicator. (Diluted beerwort requires about 20 ml. per 1 000 ml.)

"A previously prepared buffer mixture is then added as follows:—

For every 1 000 ml. of medium dissolve 12.8 g. of citric acid monohydrate and 7.2 g. of potassium citrate monohydrate in 50 ml. water and sterilise by autoclaving for 15 minutes at 120°C. Then add this buffer aseptically to the medium, which has been adjusted to approximately pH 3.5, both being at a temperature of 90°-100°C.

Medium iv.

"Adjust the pH value of the yeast salt medium to 3.5 by the addition of 5.7 g. of citric acid monohydrate per 1 000 ml. autoclaved as in Media (i), (ii) and (iii)

(c). No buffer is required.

All media.

"After thorough mixing, fill out the medium aseptically into sterile test-tubes in 10 ml. quantities. Further sterilisation is not required and shall not be attempted.

153. The products of British Drug Houses, Hopkins & Williams, Fairchild, Allen & Hanbury, Parke-Davis, Difco, and Gurr were used in the Committee's experiments.

154. For beef extract, Lemco and for yeast autolysate, Yeastrel and Marmite were used in the Committee's experiments.

"(d) *Pouring of plates*.—Melt the medium and cool to between 45° and 48°C. as soon as possible, as prolonged heating at 100°C. will destroy the gelling properties of the medium.

"(e) *Dilution*.—It is normally sufficient to plate 1 ml. quantities of the 1/10, 1/100 and 1/1 000 dilutions.

Lipolytic (Tributyrim-splitting) Organisms.

"2. Lipolytic organisms are defined as organisms whose colonies produce zones of clearing in tributyrin agar.

"There is evidence that a high proportion of organisms splitting tributyrin also split butter fat. As the rate of zone production in tributyrin is much faster than in butter fat the former has been adopted, as it permits the results to be obtained more quickly.

"The Committee's work has shown that Nile blue sulphate butter fat agar is inferior to tributyrin agar in that it gives smaller and fewer colonies.

(a) *Preparation of Medium*.

Tributyrim Agar:

Washed fibre agar.....	15 g.
Peptone ¹⁵³	5 g.
Commercial yeast autolysate ¹⁵⁴	3 g.
Tributyrim.....	10 g.
Tap Water	1 000 ml.

"The Committee's work has shown that the type of peptone used in media for the count of lipolytic organisms does not influence the result.

"Dissolve the constituents in tap water by raising to 100°C. Add the tributyrin and emulsify in an efficient emulsifying machine at a temperature of 45° to 50°C. The emulsion shall show no macroscopic globules and shall be stable. Adjust the pH value to 7.5 by the addition of HCl or NaOH with the aid of a comparator, using phenol red as indicator. Fill out in 10 ml. quantities and sterilise by steaming at 100°C. for 30 minutes on each of three successive days.

"(b) *Dilutions*.—It is normally sufficient to plate 1 ml. quantities of the 1/10, 1/100, 1/1 000 and 1/10 000 dilutions.

"(c) *Incubation*.—Incubate the plates at 30°C. for three days.

"(d) *Counting*.—On this medium, colonies with well-defined clear zones extending at least 1 mm. from the edge of the colony shall be considered to be lipolytic.

Caseolytic Organisms.

"3. These are defined as organisms whose colonies produce permanent zones of clearing in an opaque medium containing casein after flooding with a protein precipitant. Most micro-organisms attacking casein also hydrolyse fat.

(a) *Preparation of Medium*¹⁵⁵

<i>(a) Preparation of Medium</i>		
<i>Stock Solution</i>	<i>A</i> —Calcium chloride (fused).....	1.5%
<i>Stock Solution</i>	<i>B</i> { Disodium hydrogen phosphate ($\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$).....	1.05%
		Potassium dihydrogen phosphate (KH_2PO_4)... ..
<i>Stock Solution</i>	<i>C</i> —Tryptone (Difco)	5%

"Soak 3.5 g. Hammarsten's casein in 150 ml. of distilled water for 15 minutes. Add 72 ml. saturated lime water and shake until the casein has dissolved. About three hours shaking in a mechanical shaker is usually sufficient. Then add 0.35 g. of potassium citrate. Add 50 ml. of stock solution C, filter and make up to 300 ml. Add 10 ml. of stock solution A and 10 ml. of stock solution B, and make up to 500 ml. Adjust the pH value to 7.0 if necessary, using bromthymol blue as indicator. Tube in 5 ml. quantities, sterilise for 15 minutes at 120°C.

"Make up 5 ml. quantities of 3 per cent agar in distilled water and sterilise separately.

"(b) *Pouring of Plates.*—Pour the broth first, followed immediately by the 3 per cent agar, and mix the solutions well. The temperature at the time of pouring shall be 45° to 48°C.

"(c) *Dilutions.*—It is normally sufficient to plate 1 ml. quantities of the 1/10, 1/100, 1/1 000 and 1/10 000 dilutions.

"(d) *Incubation.*—Incubated plates at 30° C. for three days.

"In order to distinguish zones due to caseolysis from those due to solution of the protein by alkali formed by the organisms, flood the plates with a freshly prepared 1 per cent solution of tannic acid. If an enumeration of the total number of organisms (excluding organisms requiring sugar) is required, counting shall be done before flooding the plates.

Saccharolytic Organisms.

"4. *Chiefly lactic acid bacteria.*—To assess the number of streptococci and other sugar fermenting organisms which in some methods of butter manufacture indicate faulty methods of pasteurisation a milk serum medium may be employed. In addition to permitting growth of lactic streptococci many other common contaminants of butter, such as micrococci and coliform organisms will grow, and the count on this medium may be considered to approximate to the 'Total Count.'

(a) *Preparation of Medium.*

(i) *Milk Serum.*—Warm 1 000 ml. of fresh whole or separated milk to 40°C., add 70 ml. of 7 per cent citric acid monohydrate per 1 000 ml. slowly with stirrings, stand for 1 hour and filter overnight. Sterilise the filtrate (approximately 600 ml. at pH 4.7) by heating to 100°C. for ½ hour. Adjust to pH 6.8 before use (600 ml. requires about 40 ml. N NaOH).

(ii) *Milk Serum agar.*

Milk Serum (pH 6.8).....	1 000 ml.
Peptone.....	5 g.
Commercial yeast autolysate.....	5 g.
Dextrose.....	5 g.
Agar.....	15 g.

"To the milk serum add the other constituents, heat to 100°C. to dissolve, readjust the pH value to 6.8, using bromthymol blue as an indicator and fill out into tubes in 10 ml. quantities. Sterilise by autoclaving for 10 minutes at 120°C.

"(b) *Dilutions.*—It is normally sufficient to plate 1 ml. quantities of the 1/10, 1/100, 1/1 000 and 1/10 000 dilutions.

Coliform Organisms.

"5. There is evidence that the presence of coliform organisms indicates faults in manufacture and handling and that they affect keeping quality.

"(a) *Preparation of Medium.*

Sodium taurocholate (commercial).....	5 g.
Lactose.....	10 g.
Peptone.....	20 g.
Sodium chloride.....	5 g.
Tap water.....	1 000 ml.

"Mix the constituents, steam for 2 hours and keep in an ice chest overnight. Then filter through Chardin paper whilst still cold. Adjust the pH values to 6.8, using bromthymol blue as indicator. Add 5 per cent of 0.04 per cent aqueous solution of bromeresol purple. Distribute in 6 ml. quantities in B.S. test-tubes (152 mm. x 16 mm., B.S. 625) provided with Durham fermentation tubes (35 mm. x 8 mm., B.S. 625). Plug with

cotton wool, sterilise in the autoclave at 120°C. for 10 min., or in the steamer at 100°C. for 30 minutes on three successive days.

NOTE.—Laboratories not wishing to duplicate media may use the medium described on p. 8, Memo. 139, Foods 1937, Ministry of Health. (See page 372 of this book.)

“(b) *Dilutions*.—Dilutions of 1/10, 1/100 and 1/1 000, each in triplicate, shall be used when an estimation of coliform organisms (presumptive) is required. If acid and gas are observed in two tubes at any dilution the result shall be regarded as positive at that dilution.”

Butter Examination With the Burri Film Technic. The technic of the Burri film has been given on page 334 of this book. Long and Hammer¹⁵⁶ examined butter bacteriologically with an adaptation of the Burri smear culture technic which consists of picking small amounts (approximately 1/20,000 gram with a needle and spreading each on the surface of a dry agar slope. The bacteria in various types of butter were often found to be very irregularly distributed, both from the standpoint of numbers and colony types. The colonies on the slopes were well differentiated since they all developed on the surface of the agar. In some instances colony types were found on slopes which were not evident on plates.

Plate Counts of Butter. These have not been of as much value as have plate counts of milk. Pont¹⁵⁷ analyzed the experimental error in plate counts of butter and found just about what has been found to be true for plate counts of other foods. The plate count was not always found to be a reliable index of bacterial population. In some cases wide variations were found. Before using plate counts in research projects, this report should be carefully studied.

MICROSCOPE METHODS OF BACTERIOLOGICAL BUTTER ANALYSIS

The advantages of microscope methods over the older plate methods have prompted attempts to use them for determining the number of bacteria in butter. Hedrick¹⁵⁸ found microscope methods to be fairly accurate for distinguishing butter made from excellent cream, but not reliable for lower grades. He explained this difference on the basis that low-grade butter is not always due to bacterial action. Hedrick used the Fay method for preparing cream slides. He was able to satisfactorily grade cream and butter.

Hammer and Nelson's¹⁵⁹ Method for Microscope Bacteriological Examination of Butter. This method was used by the authors for following the changes resulting from storage of butter under different conditions. Hammer and Nelson stated that the methods of sampling butter proposed by the Special Committee on Bacteriological Methods of Analyzing Dairy Products of the American Dairy Science Association, were satisfactory. They outlined their method as follows:

1. The entire sample of butter or enough of it to yield 10 ml. of the melted product for centrifuging, is put into a beaker so that it can be readily melted and mixed. A 250-ml. beaker of the conical type is preferred, although beakers of various capacities

156. Long and Hammer. 1938. Iowa State Col. J. Sci. 12, 441-450.

157. Pont. 1941. J. Dairy Res. 12, 24-34.

158. Hedrick. 1938. J. Dairy Sci. 21, 553-558.

159. Hammer and Nelson. 1931. Iowa Agr. Expt. Sta., Res. Bull. 137.

and shapes are convenient. The melting and mixing are carried out by placing the beaker in a water bath at a temperature of from 50 to 55°C. and slowly agitating the butter, using a thermometer as a stirring rod, until the temperature reaches 45°C. (113°F.).

2. Ten ml. of the melted fat at a temperature of 45°C. are transferred to a 30-ml. separatory funnel, using a pipette that has been warmed by passing it through a flame. The size of the portion centrifuged is of no great importance, but a standard volume seems advisable and one of 10 ml. has some advantages over smaller amounts. These advantages are (1) enough serum collects to permit the removal of the serum without including any considerable percentage of fat, and (2) the volume of serum secured provides ample material for plating in case the microscope picture makes this advisable.

Centrifuging is carried out using a funnel support intended for a separatory funnel of a different shape from the one employed. A rubber stopper around the upper part of the funnel rests against the wall of the support and the funnel is carried in this way. Very little funnel breakage has been encountered and most of this has involved the tip of the funnel which projects into the lower portion of the support.

The centrifuging should throw out the serum completely without causing a separation in the serum itself. When centrifuging has been done properly the fat layer will be clear and uniform throughout. With a centrifuge in which the stop-cocks of the funnels were 14½ inches apart with the machine in operation, centrifuging one minute at a speed of 1,000 R.P.M. was found to be entirely satisfactory for the types of butter used. Samples of butter of different characters behave differently, and some types are easily over-centrifuged so that there is a separation in the serum. When this occurs a solid pack of material at the bottom of the funnel may make it very difficult to start a flow through the stop-cock and, of course, it becomes imperative to remove the serum very completely, and then thoroughly mix it, if a representative portion is to be secured for spreading on the slides. In general, centrifuging of butter made from a poor quality of cream must be carefully done or there will be a separation in the serum; presumably, this is due to the content of particles of casein or some casein derivative that readily centrifuges out. With butter made from good-quality sweet cream the centrifuging can be greatly in excess (either time or speed) of that suggested without any undesirable effect.

3. Immediately after centrifuging, the funnel is removed from the centrifuge and the serum drawn off; unless this is done before the fat begins to congeal, a great deal of difficulty is encountered. The serum should be removed very slowly so that the plane between the fat and serum is kept as flat as possible. When the serum is drawn off rapidly the portion along the wall of the funnel tends to lag and the fat is pulled down to the stop-cock when there is still a considerable percentage of the serum in the funnel. The serum is removed as completely as possible without including objectionable amounts of fat.

A short test tube makes a very satisfactory container in which to collect the serum since portions of the serum can be easily removed from it with a Breed pipette.

4. The collected serum is thoroughly agitated, and portions are removed to microscope slides with a Breed pipette. Ordinarily .01 ml. of the serum is spread over one, four, or eight sq. cm. If the area is larger than one sq. cm., sterile skim milk, free from stainable bacterial cells, or water is added with a loop to facilitate even distribution. The spreading is conveniently done with a transfer needle bent at an angle of 90 degrees. When skim milk or water is to be used it should be put near the .01 ml. of serum and thoroughly mixed with the serum before an attempt is made to cover the desired area.

The area over which the .01 ml. of serum should be spread depends on the bacterial content of the butter and the information desired. If a study of the morphologic types of organisms present is the main consideration, it is an advantage to have the organisms rather numerous in each field while if an estimation of the number is desired, the organisms should not be so numerous that counting is difficult. With butter having a very high bacterial content, counting may be facilitated by spreading the .01 ml. of serum over an area larger than eight sq. cm.

A card with the desired area laid out in black and surrounded by a broad red border is a great aid in the making of spreads that are reasonably exact in area and reasonably uniform in thickness. If a portion of the background is white the desired results are not so easily secured.

The slides are rapidly dried on a level surface and are well protected from flies and dust.

5. Both the regular methylene blue stain described in "Standard Methods of Milk Analysis" (10) and Newman's one-solution technic (5) are satisfactory for staining preparations of the serum secured from butter.

6. The examination of the stained smears under the oil immersion lens shows the general morphologic types and the general number of organisms present.

7. The number of organisms per ml. of butter may be estimated by (1) determining the average number per field, counting as many fields as seems desirable for the purpose in mind; (2) calculating the number per ml. of serum from the area over which .01 ml. of serum was spread and the diameter of the microscope field, and (3) dividing by 9 to change from a basis of one ml. of serum to a basis of one ml. of butter. Steps 2 and 3 may be combined for routine work.

Fay's¹⁶⁰ Microscope Method for Examination of Butter. This method was devised by Fay to eliminate some of the difficulties involved in use of the .01-ml. capillary pipette and the centrifuge and to provide a method which would lend itself to routine examination of many samples.

The butter to be examined is melted by heating to 45°C. (113°F.) for a period not to exceed 15 minutes, after which it is agitated sufficiently to insure a homogenous sample.

(a) On a standard 1 x 3 inch, chemically clean, glass slide place .1 ml. of the melted butter, one drop of xylol, and one drop of Mayer's egg-glycerine mixture. To prepare Mayer's solution equal parts of egg albumin and glycerine are mixed, thoroughly beaten, and filtered through cotton. One per cent sodium salicylate should be used as a preservative, and the solution kept in a refrigerator when not in use. Mayer's solution is used to aid in fixing the smear to the slide.

(b) With an "L" shaped platinum needle stir the butter, Mayer's solution, and xylol together until the mixture is opalescent and homogenous, then spread evenly over the entire area of the slide. It is important that the mixing of the ingredients be properly done before spreading the smear over the area of the slide. Proper mixing requires from two to three minutes.

(c) Allow the preparation to dry, and at the same time coagulate the albumin by placing the slide on a flat bottle of hot water at approximately 80°C. (716°F.) for 10 to 15 minutes.

(d) Fix the smear in 70 per cent alcohol for 10 to 20 seconds, and allow to dry.

(e) Immerse in xylol two minutes, and allow to dry.

(f) Stain in methylene blue for one minute, then wash by dipping the slide once in each of two vessels of water. Allow to dry in the air.

(g) Examine under an oil immersion lens, the field of which has been standardized to a diameter of .157 mm. The average number of microorganisms per field multiplied by 1,000,000 gives the number per milliliter of melted butter.

If it is desirable to enumerate objects large enough to be seen with the lower magnifications of the microscope, standardize the diameter of the field of the high dry objective to .351 mm. and of the low power objective to 1.57 mm.; multiply the average number of objects observed per field by the factors 200,000 and 10,000, respectively, to give the number per milliliter of melted butter. The method described in this paper has been found to be equally advantageous for the microscope examination of heavy cream.

Demeter's¹⁶¹ Microscope Method for Counting Bacteria in Butter. The following method was proposed after considering other similar methods. Three grams of butter

160. Fay. 1938. J. Dairy Sci. 18, 9.

161. Demeter. 1937. Deut. Milch. Ztg. 36, 1190-1191.

are weighed into a centrifuge tube marked 3, 6, and 9 ml. Seven ml. of xylol are added and the tube closed with a well-fitting stopper. It is then shaken for about five minutes and placed in an incubator at 40 to 45°C. (104 to 113°F.) for 45 minutes. After thorough shaking again the tube is centrifuged in an ordinary fat-centrifuge for one to two minutes. The supernatant solution of fat in xylol is poured off and five per cent sodium hydroxide solution poured in up to the mark 3. The tube is then corked and shaken until a homogeneous solution is obtained. Following the usual technic with a .01-ml. pipette slides are prepared and stained by Newman's method, with a contact time of six to eight seconds. The count of each gram of butter is obtained by multiplying the mean number of bacteria per field by 300,000. For poor-quality butter water is added to mark 6 or mark 9 and a factor of 2 or 3 used for determining the count.

The Frost little-plate method and certain modifications has also been found to be satisfactory for butter. Moir and Russell¹⁵⁰ recommended the microplate method of Johns¹⁶² for counting bacteria in butter. By staining the cultures as recommended, the results were available within 24 hours. Moir and Russell described their method in full.

YEASTS IN BUTTER

Yeasts are widespread in nature and are to be expected in butter. Their presence in butter has a two-fold interest for bacteriologists. They may indicate faulty handling of cream and inefficient pasteurization and they may cause objectionable changes in the cream which result in bad flavors and odors. Both of these problems have received much study. Lactose-fermenting yeasts are common in cream and if allowed to develop, cause a frothy fermentation. Many such yeasts have been described in milk, cream, and milk products.

Yeasts were found by Dombrowski¹⁶³ in all samples of milk and milk products. *Torulæ* were more frequent than *Saccharomyces* and *Myco-derma*. The activities of the yeasts were not limited to alcoholic fermentation. Some were found to produce colors and flavors, while others showed no fermentative activity whatsoever. Hammer¹⁶⁴ mentioned some of the difficulties in studying yeasts in butter and other dairy products and identification with species in the literature. His comments may be extended to the identification of yeasts from all sources. Similar observations were made by Hastings¹⁶⁵ for milk, whey, butter, and cheese. Yeasts were found to be widely distributed in Swiss, brick, and Cheddar cheese factories. They were also present in about one-fourth of the samples of butter examined and in 29 out of 51 samples of milk. The main sources of infection were believed to be the soil and accumulations of dirt protected from drying. This type of yeast was not considered of economic importance except in certain branches of dairying. In Swiss and brick cheese factories infection with lactose-fermenting yeasts have, in several instances, caused considerable trouble. The danger from infection with this organism is not apt to occur in Cheddar cheese making. Bochiechio¹⁶⁶ observed spoilage of Grana cheese by a yeast which fermented lactose. The yeast was checked

by a temperature of 55°C.(131°F.) to 60°C.(140°F.), so that infected utensils could be readily cleaned with boiling water. The name suggested by the author for this yeast was *Lactomyces inflans caseigrana*.

Effect of Pasteurization on Yeasts in Cream. Yeasts are not as resistant to heat as bacteria and consequently it has been suggested that their presence in butter might indicate that pasteurization was inefficient. Dougherty¹⁶⁷ and Wells¹⁶⁸ have both demonstrated that most yeasts are destroyed at 61°C.(141.8°F.). Dougherty found only three species which survived this temperature under the conditions under which she worked. Hunziker *et al.*¹⁶⁹ stated that the efficiency of pasteurization of cream at 73.9°C.(165°F.) for 30 seconds in killing yeasts and molds was 78 per cent, while at 85°C. (185°F.) for 30 seconds or 62.8°C.(145°F.) for 30 minutes the efficiency was 99.9 per cent. Lund¹⁷³ found that nearly all yeasts were destroyed at 62.8°C.(145°F.) in 30 minutes. Macy, Coulter, and Combs¹⁷² found that yeasts were destroyed in 71 per cent of cream samples by pasteurization. Bouska and Brown¹⁷⁰ stated that if butter which purports to have been made from pasteurized cream contains hundreds of yeasts or molds they would hesitate to say that pasteurization had fulfilled its usual hygienic or commercial requirement, nor would they agree that it could be marked as pasteurized.

Stiritz,¹⁷¹ on the other hand, reported that the yeast and mold counts cannot be regarded as an index of efficient pasteurization. However, Stiritz was willing to accept a standard of 30 colonies per ml. as the maximum number allowable for a butter prepared under suitable conditions. No information was yielded by the yeast and mold count on the question as to whether the butter was made from raw or pasteurized cream. After pasteurization the churn was said to be a source of contamination. This has also been reported by others.

Prevalence of Yeasts in Butter. Much of the butter formerly made in the United States contained many yeasts. This was due largely to lack of adequate methods of refrigeration and to faulty processing of the cream. Pasteurization of the cream reduced the yeast content of the butter but did not eliminate them.

Samples of butter examined by Lund¹⁷³ showed from 350 to 4,000 yeasts per ml. in the unpasteurized cream butter. In pasteurized cream butter the yeast count varied from 60 to 5,000, except in one sample which contained 5,000,000. The yeast content of butter was said to come from contamination in the churn. In a later paper, Lund¹⁷⁴ stated that pasteurization would reduce the *Oidium* counts, but the yeast counts often were high. Again he stated that the yeast contamination resulted from the churn and not from the fact that the yeasts survived pasteurization. Lund ex-

aminated, in one case, seven specimens of creamery butter made from raw cream, and four from imperfectly pasteurized cream. An average yeast count of 1,700 per ml. was reported. Ten samples of butter from pasteurized cream gave a yeast count of 1,182. Further work by Lund¹⁷⁵ on butters submitted in a scoring contest revealed a high yeast count, and confirmed his former statements; he considered the churn to be the most insanitary piece of apparatus in the modern creamery. Sandelin¹⁷⁶ found *torulae* to be common in butter. He classified the strains which he studied, according to the substances which they attacked. Bouska and Brown¹⁷⁰ reported that the butter from creameries using a pure starter and thorough steaming of equipment had a low yeast content and kept better. Since contamination with yeasts may result from the churn, Stiritz¹⁷¹ believed that yeast and mold counts of finished butter could not be taken as an efficiency index of pasteurization, or as a method for determining whether butter has been made from raw or pasteurized cream. North and Reddish¹⁷⁷ studied the presence of yeasts in samples of butter scoring 93 or over by Redfield's microscope method. They found yeasts to be more evenly distributed than *Oidia*. Redfield¹⁷⁸ made similar observations on butter of slightly lower grade. Redfield reported that, in general, low-grade samples of butter showed high counts of yeast, but this was not always the case, indicating that other factors were also responsible for deterioration. Redfield believed that there was some relation of high yeast counts to the condition of the cream used in manufacture of the butter. Neither salt content nor acidity affects yeast growth in fresh cream butters (Gilmour and Curess-Callaghan¹⁷⁹). Growth increased as the temperature was higher but was stopped at $-7^{\circ}\text{C.}(19.4^{\circ}\text{F.})$.

Significance of Yeasts in Butter. Yeasts in butter have about the same significance in butter that molds have, *i.e.*, bad "housekeeping" in the creamery. Their presence may be due to cream which has been mistreated, to insanitary utensils and apparatus, and to lack of refrigeration of both cream and butter. Dust owing to poor ventilation may also be a contributing factor. Lund's experience with the yeast count indicated that it could be used for determining whether butter had been made from raw or pasteurized cream. Macy¹⁸⁰ believed that the yeast and mold counts reflected the care which had been used in making the butter.

Relation of Yeast Count to Keeping Quality of Butter. While a number of investigations have been carried out on this subject, the conclusions which have been reached are neither convincing nor in agreement. Lund¹⁸¹ found large numbers of yeasts in butter but could not definitely relate them to keeping quality. Bouska and Brown¹⁷⁰ believed that a butter with few yeasts and mold was a safer hazard for long shipments and storage.

Their experience showed that creameries with low yeast and mold count butter, had better commercial reputations. These, in general, were the conclusions reached also by Grimes,¹⁸² Shutt,¹⁸³ and North and Reddish.¹⁷⁷ Anyone familiar with the physiology of the yeasts would expect some of them, at least, to be injurious to butter. The differences of opinion on this question may be easily explained by the fact that different species may have been predominant in the specimens which were used by the several investigators. If the predominating species were injurious, yeasts were said to harm butter. This problem probably ought to be approached from the pure culture viewpoint.

Because of differences of opinion among investigators with respect to the proper medium for counting yeasts Parfitt¹⁸⁴ compared several different ones. The results of the study showed that whey agar prepared by rennet coagulation produced the lowest yeast and mold counts. The differences between the dehydrated agars prepared by a commercial concern were slight. In order to secure comparative yeast and mold counts it was found that either dehydrated whey, malt, or wort agars should be used. Shadwick¹⁸⁵ found that proper adjustment of reaction of media to pH 3.5 was necessary in order to eliminate bacteria which otherwise confuse observations on yeasts. Potato dextrose agar, especially the dehydrated product of the Digestive Ferments Company, gave better results than did dehydrated malt, peptonized milk, whey or wort agars. Other factors were investigated by Hood and White.¹⁸⁶ No significant differences in counts were attributed to pH from 3 to 4.6 of agar medium incubated for five days at 25°C. (77°F.). White and Hood recommended a pH for the plating medium of ± 3.5 . Temperature of incubation should be 25°C. (77°F.). They believed standard times and temperatures should be used.

Redfield's¹⁸⁷ Method for Counting Yeasts in Butter. Redfield modified Breed's microscope method for estimating yeasts and *Oidia* in butter and cream. He described his technic as follows:

Butter: By means of a small butter trier, three or four cores from different portions of the butter sample are transferred to a six by one inch test tube, usually about half filling the tube. The butter is melted at 45°C. (113°F.) and allowed to stand at temperatures between 45°C. (113°F.) and 40°C. (104°F.) until the fat is separated in a clean layer with mixture of curd and whey or brine at the bottom of the tube. With a sterile one ml. pipette the curd and whey are thoroughly mixed by drawing the liquid back and forth in the pipette. Then one ml. of this mixture is transferred to a clean watch glass, care being taken to thoroughly wipe all fat from the outside of the pipette with a clean towel before discharging the pipette into the watch glass. With a Breed Pipette .01 ml. of the mixture is transferred to a microscope slide, carefully spread over an area of two or four sq. cm. depending on the quality of the butter, diluting if necessary with distilled water to obtain uniform smears. After drying in the air, extracting with xylol, and fixation with 95 per cent alcohol, the smears are stained with saturated aqueous methylene blue after which they are washed with water and then with 95 per cent alcohol and dried in air.

183. Shutt. 1929. Sci. Agr. 9, 316-320.

184. Parfitt. 1933. J. Dairy Sci. 16, 141-147.

185. Shadwick. 1938. Food Research 3, 287-298.

186. Hood and White. 1931. J. Dairy Sci. 14, 463-476.

187. Redfield. 1922. J. Dairy Sci. 5, 14-21.

Counting is done with a combination of lens and draw-tube length to give a factor of 500,000. The diameter of the field should be .16 mm. to give this factor. Redfield recommended counting at least 100 fields except in very high count products.

Shutt's¹⁸⁸ Method for Determining Yeasts in Butter. Shutt, in a personal communication to the author, outlined the following procedure for determining yeasts in butter:

Apparatus required:

Sterile screw-top jars, sterile butter irons,¹⁸⁹ sterile water blanks of 90 ml., sterile Petri dishes, sterile pipettes, 10 ml. and one ml.

Sampling. With a well-boiled and cooled butter iron remove a plug of butter from the print or solid and transfer the plug, less the top half-inch, to the sterile jar. If sample must be held it must be kept in cold storage for not longer than 36 hours.

Method of Analysis. Place the water blanks and the samples of butter in a warming chamber at 41°C.(105.8°F.) until the water blanks are warm and the butter is melted. Shake the butter well.

Transfer 10 ml. of the melted butter, with a warmed pipette, to a 90 ml. warm water blank and shake 25 times. Make further dilutions if required.

Transfer one ml. of each dilution including original butter to Petri plates and pour with acidified malt extract agar.

Incubate all plates at 25°C.(77°F.) for four days.

Count all yeast colonies and record.

American Public Health Association¹⁹⁰ Procedures for Determination of Yeasts and Molds in Butter. Since butter cultures are added to cream to be made into butter, a plate count cannot be used for determining its sanitary condition. Consequently, in search for a microbiological method which could be used, bacteriologists have considered yeasts and molds as possible indicators of faulty conditions of manufacture. If these organisms are used in this manner it must be on the premise that they should be present in significant numbers in bad butter and absent in good butter made from adequately pasteurized cream.

The first instructions concern collection and handling of the sample. A sterile trier is recommended for taking two or three samples from each lot. These are transferred to sterile sample bottles and kept below 40°C.(104°F.) before analysis. Where many samples are to be collected, a single trier may be used if it is wiped clean, dipped in alcohol, and the latter ignited between each sample.

The sample jar with samples, just before analysis, is placed in warm water between 40 and 45°C. (104 and 113°F.) to melt the butter. The time should not exceed 15 minutes.

Dilutions are made in sterile water in dilution bottles using sterile 11-ml. pipettes. These are warmed by drawing into them some of the warm dilution water (40 to 45°C.) and letting it run back into the bottle. Then place 11 ml. of the melted sample in the 99-ml. dilution bottle. Plate as for milk with such dilution that fat in the dishes will not interfere with colony counting.

The medium is dextrose-potato-agar and the plates should be incubated for five days at 21 to 25°C. (69.8 to 77°F.). At the end of this time count the number of yeast and mold colonies.

British Standard Methods¹⁹¹ for Determination of Yeast and Molds in Butter. These procedures are not very different from those recommended by the American Public Health Association. After the sample has been collected and melted at a temperature not exceeding 45°C.(113°F.) a 1-10 dilution is made by transferring 10 ml. of melted sample to 99 ml. of sterile water. This mixture is then well shaken. Subsequent dilutions are to be made by transferring one ml. of this 1-10 dilution to nine ml. of sterile water at room temperature.

188. Shutt. 1924. J. Dairy Sci. 7, 357-360.

189. While it is desirable to use absolutely sterile butter irons, Shutt stated that the irons could be boiled and cooled when samples are collected away from the laboratory. This would insure freedom from yeasts and molds even though all bacteria might not be killed.

190. Amer. Pub. Health Assoc., Standard Methods for the Examination of Dairy Products, Eighth Edition. 1941. New York, N. Y.

Plates are poured in the usual manner using either beerwort agar, malt extract agar, dextrose agar, or yeast salt agar media. The plates should be counted after incubation for three days at 25°C. (77°F.).

Johns' Method for Determining Yeast Count of Butter. This is described below on page 495.

Yeast Count Standards for Butter. These should be established only after adequate observations on good and poor butters. Only a few have made suggestions. Based on study of conditions of production and yeast and mold counts Parfitt¹⁹¹ proposed standards as follows. Less than 50 yeasts and molds per milliliter of butter representing good conditions of manufacture; 51 to 100 ml. representing fair conditions; 101 to 500 per ml. representing poor conditions; and over 500 per ml. representing very poor conditions of manufacture.

Brandt¹⁹² graded butter with the yeast count as one criterion of quality. Samples held for five to six days at 10 to 12°C. (50 to 53.6°F.) containing more than 150,000 yeast cells and more than 400,000 bacteria were graded as poor.

Olson and Hammer's¹⁹³ Agar Disc Method for Studying Contamination From Metal Surfaces. This method was developed for studying the microbial condition of the surface of churns. The method should also be useful for studying other surfaces.

a. After melting and cooling to approximately 43°C., the special medium (about 10 ml.) is poured on a small area of the surface to be examined and allowed to solidify. The medium that has been used is beef-infusion agar made with 2.5 per cent of air dried agar so that the disc will be strong enough to permit handling. Other media can be employed and perhaps are advisable for some purposes.

b. The agar disc is picked up with a sterile spatula and tipped into a sterile petri dish so that the portion of the disc that was in contact with the surface being examined is toward the top of the dish.

c. The disc is incubated at 21°C. for four days, although if the disc is so heavily seeded that there is danger of the colonies fusing, the incubation period is shortened. The incubation conditions can be varied for special purposes.

d. The colonies developing on a measured area (usually 20 to 30 sq. cm.) are counted and the results expressed as the number per square centimeter. With very heavily seeded discs, either approximate counts or estimates are accepted.

Wildman's Agar Slice Method for Detection of Mold and Yeast on Utensils. The Hammer-Olson method just described for determining presence of microorganisms on surfaces was not considered by Wildman¹⁹⁴ to be suitable for conditions under which Wildman was working. He used slices of agar medium described below. The slice may be placed on the surface to be examined, picked up, and stored in a suitable container for further observation.

METHOD

Preparation of Materials: Straight-edged test tubes of a convenient size (three-fourths inch to one inch, outside diameter) are selected and a small opening made in the bottom of each. The tubes are then corked, cotton-plugged tightly in the small opening, both ends wrapped with tin foil, and sterilized with dry heat. After sterilization, the tubes are filled with sterile, acidulated, potato-dextrose agar (2.5 per cent agar), corked, and quickly inverted. The tin-foil wrappings are replaced and held with rubber bands.

A supply of small petri dishes, or metal salve boxes, and double-edged razor blades are sterilized. Salve boxes (one-fourth ounce) fitted with small squares of glass held

in place by means of paraffin have proved satisfactory for holding the agar slices during observation periods. New razor blades may be sterilized in the original carton and each blade broken in two lengthwise before unwrapping. Used blades may be wrapped and used again.

Operation: A tube of solidified agar is prepared for use by removing the small cotton plug aseptically and replacing the tin-foil cap. The agar core is allowed to slide out of the tube approximately one-eighth inch and a disc is sliced off with a sterile blade. The disc may adhere to the blade after slicing. In order to facilitate its placement in the utensil under test, it may be pushed to the extreme end of the blade with a sterile edge of the test tube. The slice should be pressed down with the blade in order to secure contact of slice and utensil, after which the disc is removed by sliding the blade between disc and utensil and placed in the salve box contact side up. The disc should be examined at 24-hour intervals since yeast or *Oospora lactis*, when present, develop rapidly but may be overgrown later with air-borne molds. A wide-field binocular microscope of the Greenough type, having a magnification of 20-30, has been found to be a useful aid in the examination.

Precautions should be taken at each step to insure freedom from contamination of agar core, ends of tube, and agar slice.

Wildman used this method in an investigation of relative abundance of *Oospora lactis* on utensils used in production of cream.

MOLDS IN BUTTER

Mold counts of butter have become an important part of laboratory control. High mold counts reveal unsatisfactory plant processing methods and sanitation. Hood¹⁹⁵ listed the main sources of molds as inefficient pasteurization and raw cream recontamination; dead ends in pipes; improperly cleaned and sterilized vats, pumps, pipes, and churns; impure water; improperly treated parchment linings; unseasoned butter boxes; and damp storage. Attention must be given to all of these if butter is to be produced with a low mold count. Cream may be a rich source of molds. Even though they are killed by pasteurization, the cream may be contaminated again or the butter contaminated during preparation for distribution.

Effect of Pasteurization of Cream on Molds. Mold spores are, in general, less resistant to heat than spores of other microorganisms. Thom and Ayers¹⁹⁶ were among the first to give serious study to the effect of pasteurization on molds in cream. They used spores from cultures of various molds, including several species of *Penicillium*, *Aspergillus*, and *Mucors*, with, in some experiments, the addition of *Oidium lactis* and one strain of *Fusarium*. These experiments were made to test the temperatures used in pasteurization by the holder process, and the effects of dry heat. In the holder process of pasteurization, in which milk was heated to from 48.9 to 65.6°C. (120 to 150°F.) and maintained at these temperatures for 30 minutes, the *Mucor racemosus* group and *Rhizopus nigricans*, which are found more frequently than all others of the *Mucor* group combined, were destroyed at 54.5°C. (130°F.); a few withstood 57.2°C. (135°F.), and two, one of them an undescribed soil organism, survived 60°C. (140°F.) for 30 minutes. Among species of *Aspergillus*, however, the strains of *Aspergillus flavus*, *Aspergillus fumigatus*, and *Aspergillus repens* all survived 62.8°C.

195. Hood. 1941. *Canad. Dairy and Ice Cream J.* 20, 29.

196. Thom and Ayers. 1916. *J. Agr. Res.* 6, 153-166.

(145°F.) for 30 minutes; and *Aspergillus repens* and *Aspergillus fumigatus* both survived 65.6°C. (150°F.). These three species are always found in forage and feeding stuffs; hence, milk is more or less subject to contamination with them. *Aspergillus repens* grows very poorly in milk, however, and the examination of a great many cultures of milk and its products has shown that the actual development of *Aspergillus flavus* and *Aspergillus fumigatus* is comparatively rare. Pasteurization of milk at 62.8°C. (145°F.) may, therefore, be regarded as destroying mold spores completely enough to render them a negligible factor in the further changes found in the milk.

In the flash process of pasteurization, where milk was heated to from 62.8 to 79.4°C. (145 to 175°F.) for a period of 30 seconds, the spores of all the molds tested were destroyed with the exception of many spores of one form and occasional spores of three more forms. At 79.4°C. (175°F.) only occasional spores of two forms developed.

When the heating process was performed in dry air for a period of 30 seconds at 93.3°C. (200°F.), 31 out of 42 forms of *Penicillium* and seven out of 24 forms of *Aspergillus* were destroyed, but none of the cultures of the *Mucors*. A temperatures of 121.1°C. (250°F.) over a period of 30 minutes killed all the forms of *Penicillium* species tried, but left an occasional living spore in one species of *Aspergillus* and three out of six *Mucors*.

Careful study of the cultures showed that the first effect of heating was to delay germination. At times, heating to a degree just under the death point delayed germination almost the full length of the usual growing period of the species. There is, frequently, a survival of a few spores where a majority die. There may be, therefore, a difference of as much as 20°C. (36°F.) between the temperature at which an occasional culture is completely killed and that at which cultures of that species are uniformly killed. These results resemble those obtained in determining thermal-death point of bacteria. Macy and Combs¹⁹⁷ stated that in 40 per cent of the supposedly pasteurized cream, the mold has not been destroyed. Approximately 90 per cent of the dry parchment and cloth circles carried mold spores. Pipes, churns, pumps, liners, starter, and salt were important sources of mold contamination of butter.

The good effects of pasteurization may be offset in a large way if cream is contaminated afterwards by careless handling. Molds in Canadian butter made from pasteurized cream was attributed by Hood and White¹⁹⁸ to this. Unclean utensils played a role here. According to Lund,¹⁹⁹ butter made from unpasteurized cream may contain from 10 to 7,000 spores per ml. Spores of *Oidium lactis* were destroyed by exposure to 54.4°C. (130°F.) for 30 minutes. Lund, therefore, believed that the presence of these organisms could be used as an index of efficient pasteurization. Nicholls,²⁰⁰ on the other hand, observed that *Oidium lactis* might survive pasteurization for short periods at 76.7°C. (170°F.). Results of investigations by Gibson and Tanner and Hofer, reported in Chapter 3, indicate that most strains

would be destroyed by pasteurization as usually carried out. Lund¹⁷⁵ found less than 10 colonies of *Oidium lactis* in 63.5 per cent of Canadian and 70 per cent of Ontario butter made from pasteurized cream.

Significance of Molds in Butter. Presence of large numbers of molds in cream indicates bad handling. Should they grow to any extent bad flavors and odors result. Vandaveer and Wildman²⁰¹ associated high acidity of cream with a high mold-mycelium count; sweet cream or a good sour cream usually produced butter with a zero or low mold-mycelium count, while butter made from a high-acid cream almost invariably had a high mold count. This was considered to prove conclusively that decomposed or unfit cream was used. Macy²⁰² concurred in this opinion. The above discussion refers to mold spores which may develop into mycelia if the butter is not stored properly.

Adams and Parfitt²⁰³ believed that mold-mycelia fragments in butter are an index of the length of time of storage, temperature of storage, and oxygen relationship of the cream from which the butter was made. Mold mycelia in butter is not an direct index of the organoleptic quality of the cream from which the butter was made. A higher percentage of mold mycelia than of bacteria is retained in the butter. In general, the retention is 20 to 30 per cent. Of the manufacturing operations studied none was found to influence significantly the mold-mycelia content of butter. Thom and Shaw²⁰⁴ believed that the presence of the species *Alternaria*, *Oidium*, and *Cladosporium* indicated low salting. Excess of curd favored the development of molds; well-washed butter was less subject to development of mold. To prevent the development of molds, Thom and Shaw believed that butter should be carefully packed and stored under proper conditions.

Mold and yeast counts have been believed by some to be related to keeping quality of butter. Macy and Ritchie²⁰⁵ found the relationship to be indefinite since counts of these microorganisms were not reliable indices of keeping quality under all conditions. Similar conclusions were reached by Vernon,²⁰⁶ who observed only slightly better keeping quality of butter with low yeast and mold counts. Vernon believed that it was the activity of the mold which was important. Some molds grow in butter and produce products which affect quality, while others may be present only as viable spores and have no effect on quality. In the mold count both types receive equal emphasis. Vernon²⁰⁶ believed, further, that an attempt might be made to learn something about the activities of molds in butter—whether they were lipolytic or caseolytic. The mold counts as determined today are indications of bad practice in handling cream and methods of making and handling the butter. Lower counts indicate good “house-keeping.” Groth²⁰⁷ gave moisture much significance and, therefore, sug-

gested good ventilation and even drying of air in creameries. In addition attention should be given to many little things in the creamery, all of which are good practice under any conditions. *Oidium lactis* is a fungus prone to be prevalent in butter. Redfield¹⁸⁷ found it to be especially prevalent in low-grade butters. He believed the churn to be the source of the fungus. Samples of butter with lower yeast and mold counts keep a little better than those with higher counts (Vernon²⁰⁸). The count, however, may not be all that is involved. The activity of the fungus is just as important. Some molds grow in butter and produce products which cause bad odors and flavors while others have no effect on quality. Both types receive the same consideration in the mold count. Qualitative counts are fast receiving attention due them. The present yeast count is only an indication of plant methods.

Species of Molds Found in Butter. As would be expected these are quite varied and represent most of the common genera. Cream and butter pick up molds from every agent with which they come in contact. Various species have been identified by Boekhout and van Beyum,²⁰⁹ Olson and Hammer,²¹⁰ and Grimes *et al.*²¹¹

Factors Involved in Mold Growth in Butter. These are several in number, such as salt content, hydrogen-ion concentration, presence of casein, and water content. Most of them have been investigated at one time or another. Development of *Penicillium glaucum* is stopped according to Voitkevitch²¹² in nutritive media at 27 per cent concentration of sodium chloride and 83 per cent relative humidity, while a 12-per cent concentration of sodium chloride, and 92 per cent humidity have the same effect on *Oidium lactis*. The quantity of spores inoculated into butter does not affect the rapidity of their development; high humidity favors their development. Salting butter decreases the percentage but does not prevent the development of molds. High acidity of the butter correlates with increase of molds. An attempt was made by Thornton and Wood²¹³ to relate mold growth on the surface of butter to condensation moisture on the surface. They considered it improbable that mold growth started in incorporated moisture of salted and unsalted butter. *Cladosporium* sp. was isolated from butter showing interior type of molding.

Sources of Mold in Butter. Results of many investigations indicate that molds may reach butter from many different sources. Some have suggested that the mold content of butter might be accepted as the sole measure of its sanitary qualities, with which Wood and Thornton²¹⁴ disagreed.

Thorough sanitation seems to be the best solution of the mold problem. Macy and Combs,¹⁹⁷ Hood and White,²¹⁵ Macy and Ritchie,²⁰⁵ and Macy²¹⁶

supported this opinion. Mendelsohn, McCoy, and Long²¹⁷ believed that a mold-free butter could be made in a well-operated creamery.

Cream. This has been shown to be a fertile source of many of the molds in butter. Field surveys by Macy and Combs¹⁹⁷ revealed that raw cream is usually heavily contaminated with molds even though it may seem to be sweet and fresh. In 40 per cent of the supposedly pasteurized cream, molds had not been destroyed. About every article with which the cream comes in contact may contribute molds to it. Adams and Parfitt²⁰³ also showed the close relationship which may exist between mold content of cream to mold content of the butter made from it. From 20 to 30 per cent of the mold mycelia in cream is retained in the butter.

Parchment Paper. This article has often been blamed, and probably rightfully in many cases, for surface defects, especially mold spots, of butter. Vernon²¹⁸ stated that surface taint of butter has been termed "parchment flavor" by some in trade circles. Although methods of manufacture should give a practically sterile paper, contamination during cutting, packing, and shipment is possible. Under proper conditions these molds may develop on the paper and infect butter wrapped in it. Should certain ingredients be incorporated in parchment for any purpose, growth of molds may be enhanced. Glycerol, according to Vernon, stimulates spore formation and is a good food for molds. Its hygroscopic nature assists development of molds and limits the value of low temperatures in repressing them. Glycerol-treated parchment molds sooner and to a greater extent than glycerol-free paper. Salt-softened parchment does not inhibit mold growth unless high concentration, not commercially possible, is used. Parchment treated with five or 10 per cent salt solution is attacked by some common molds more easily than untreated papers. Where parchment has been carefully studied, as it has been at the University of Minnesota by Macy²¹⁹ and his colleagues, it has been found to be a troublesome source of molds. In some of their experiments, butter produced under aseptic conditions was wrapped in contaminated and sterilized parchment. Part of it was stored at 12.8°C.(55°F.) and the remainder at 4.4°C.(40°F.). Some was also stored in moist stagnant air which greatly favored mold development. No molds appeared even after 90 days on the butter wrapped in treated parchment. Butter wrapped in untreated parchment molded in 48 to 70 days at 12.8°C.(55°F.) and in 60 to 90 days at 4.4°C.(40°F.). The parchment became contaminated from dust and careless handling. Attempts to solve this problem in the early days involved boiling in water for 10 minutes or a brine containing three to five pounds of salt per gallon. The paper was then left in this container until used. Reports of exhaustive experiments were reported a year later by Macy and Pulkrabek.²²⁰ The treatment just recommended was enlarged upon and other methods involving use of chemicals were discussed. It was apparently

more difficult to control surface molding when the butter itself was the source of the fungi.

Macy and Olson ²²¹ reported marked inhibition of molds on butter deliberately contaminated with mold spores by wrapping in parchment paper which had been treated with sodium or calcium propionate. The inhibition was much more pronounced with salted butter. Parchment is now available for this purpose. One is known as "Mycoban," treated parchment containing six per cent of calcium propionate on the basis of the dry weight of the paper. Creameries also treat paper to be used for lining tubs. Vast amounts of butter are packed today in such paper.

Butter Boxes. These are wooden boxes used for butter in bulk. They are subject to attack by molds, for the wood holds moisture and may even become saturated with various substances which molds like and need in their metabolism. Vernon ²²² recognized these boxes as important sources of molds.

The most important source of infection is thought to be the condensation water accumulating in boxes of butter after removal from cold storage. As a rule, the temperature conditions obtaining in transport and storage are sufficiently low to prevent fungal development, but on removal from storage after four months the molds are capable of almost immediate resumption of growth. Glycerine and salt are frequently used to treat parchment wrappers for Australian and Danish butters, respectively; both were found (contrary to expectation in the case of salt) to increase susceptibility to mold infection. Experiments carried out in New Zealand by Riddet and Neill ²²³ showed that molds (*Pullularia pullulans*, *Cladosporium herbarum*, *Penicillium expansum*, *Mucor* sp., and a red-staining type) originating in butter boxes may infect the surface layer of butter packed therein and cause extensive damage. Mold growth on the boxes was stimulated by defrosting the butter at high atmospheric temperature in air of high humidity, by admitting air to the inner surface of the box, and by the use of sapwood in place of heartwood and of rotary-cut instead of sawed wood. The "springing" of the sides away from the ends of boxes during handling and the consequent admission of air stimulated mold growth. Swedish pine impregnated with wax was less susceptible than white pine, but imparted a taint to the butter. Immersion of the wood in .1 per cent sodium salicylanilide solution for 10 minutes gave very promising results in preventing infection.

Churn. The churn has been found to be a prolific source of molds and other microorganisms if it is not thoroughly and properly cleaned. Observations were made on two churns by Macy, Combs, and Morrison, ²²⁴ one of which had been used for 10 years in a creamery where considerable difficulty with mold had been experienced and the other in the experiment station creamery where it had been in daily use for seven years. A large

225. Morrison, Macy, and Combs. 1931. Idem, 404-415.

number of samples collected from the first churn showed the presence of many molds and a wide variety of species while those from the second churn were relatively free from molds; those which were found were members of only five genera. Having determined this situation, Morrison, Macy, and Combs studied procedures for removing them from churns. Steam and hot water when used regularly were found to yield satisfactory conditions. Little success was secured with such disinfectants as sodium hypochlorite, alkaline crystalline hypochlorite, and chloramine-T. The same conditions in churns were observed by Olson and Hammer.¹⁹³ Wide variation in their microbiological condition existed with bacteria usually more numerous than yeasts and molds. Striking reductions in number of microorganisms were accomplished with hot water. Yeasts and molds were largely eliminated. Solutions of sodium hypochlorite and chloramine preparations seemed to be less satisfactory. Bendixen²²⁶ found that quite stringent methods had to be used to rid churns of molds. Chemical disinfectants cannot be added to butter but may be used on utensils.

Water and salt are other agents which may contribute molds to butter. Mold spores are ubiquitous and may easily be picked up by water. Unless salt is handled in a cleanly manner, it may harbor large numbers of mold spores. It should not be stored in bulk on the floor as it once was in many preservation plants. Sweepings and dust contribute various microorganisms in large numbers.

Prevention and Control of Molds in Butter. Damaging outbreaks of moldy butter have prompted many investigations as to cause and means of prevention. The investigations of Hood and White¹⁹⁸ revealed two possible methods of preventing moldy butter: (1) preventing ingress of molds into butter during manufacturing and (2) preventing development in case they have entered. Among those who early emphasized the need of strict cleanliness in the creamery was Hastings.²²⁷ Practically all who have worked on this problem have stressed strict sanitation as the bacteriologist defines it.

Various investigators have reported that salt may be used to inhibit molds in butter. Thom and Shaw²⁰⁴ stated that species of *Oidium*, *Alternaria*, and *Cladosporium* cannot develop in butter containing 2.5 per cent of salt. Consequently, they believe that occurrence of any of these forms in butter meant low salting. About the same species were reported by Morgan²²⁸ in unsalted butter. They observed germination of spores, however, in much more concentrated salt solutions than others have reported. Distinction should be made between concentrations of salt in butter and in brine. Mold spores may be exposed to fairly high concentrations of salt in butter because it concentrates in the water phase only. Development of *Penicillium glaucum* occurred in Voitkevich's²¹² experiments at 27 per cent concentration of salt and 83 per cent relative humidity, while 12 per cent concentration and 92 per cent relative humidity had the same effect

on *Oidium lactis*. Salting of butter reduced mold growth but did not prevent it. High humidity was a factor which favored it.

METHODS FOR DETERMINING MOLDS IN BUTTER

Examination of butter for molds may involve either cultural methods for actually enumerating the living fungi which are present in examination of the butter for mold mycelia. Mere presence of molds which will develop in culture media and on plates may not have much significance unless they are present in large numbers or possess most undesirable characteristics which will affect the color and flavor. Examination for mold hyphae is usually a microscope technic based largely on the Howard method for demonstrating molds in tomato products. Results of this examination tell whether the cream and butter have been mishandled either by being held at too high temperatures, held in dusty creameries, handled in unclean apparatus, or wrapped in mold-infested parchment. Other factors may also be involved. The Howard method reveals the presence of mold filaments which have resulted from careless practices. Some of the other methods tell whether mold spores are present which may develop into hyphae.

Johns' ¹⁶² Method for Determining Mold and Yeast Count of Butter. This method is an adaptation of the Frost little-plate method for determining the number of bacteria in milk as described on page 354. After considerable preliminary work, Johns gave the following detailed description of technic:

Samples of butter are obtained by drawing three or four plugs with a sterile trier discarding the top one-half inch in each case, and transferring the remainder to a sterile sample jar. Jars are set in a water bath at 40-45°C. (104-113°F.) until melted. When completely melted, sample is shaken vigorously for 30 seconds, and a 10-ml. portion withdrawn with a sterile warmed pipette. After removing the butter from the outside of the pipette with a sterile cloth or paper, the contents are delivered into a dilution bottle containing 40 ml. of sterile water warmed to 45°C. (113°F.). (A 250-ml. Erlenmeyer flask may be substituted for a dilution bottle; or two ml. of butter may be added to eight ml. of water in a 16 × 150 mm. test tube. These substitutes are less convenient for shaking and mixing.)

While the samples are melting, an area of two by four cm. is marked out upon clean microscope slides with a wax pencil. A small metal box or tank, insulated upon the sides and bottom, is filled with water at 45°C. (113°F.); this is used as a "warm table" to prevent hardening of the agar medium before it can be mixed with the diluted butter being plated. A tube of previously melted wort agar acidified with sterile lactic acid to pH 3.5 to 4.0 is placed in the water through a hole in the top of the warm table, to maintain the proper temperature.

Duplicate slides are flamed and placed upon the surface of the warm table. The dilution bottle is shaken vigorously for 30 seconds, and a one-ml. pipette, graduated in tenths, filled to the upper graduation. After wiping off the exterior with a sterile cloth or paper, .2 ml. is delivered on to the marked area of each slide. Four drops of agar are added to each, thoroughly mixed with the diluted butter, and spread evenly over the area with a sterile needle. The microplates are removed to a cold level surface and covered to protect them from air contamination while hardening. When hardened they are transferred to a sterile moist chamber for incubation. (A convenient form of moist chamber is listed by the Central Scientific Co. for milk analysis with the Frost technique.) An incubation period of 12 to 18 hours at 25°C. (77°F.) has been found most suitable, and fits in well with ordinary laboratory routine. Where a shorter period must be used, it is advisable to raise the temperature to 30°C. (86°F.); conversely, with a period in excess of 18 hours, a lower temperature is desirable.

At the conclusion of the incubation period the microplates are removed and "dried down" upon a metal sheet placed over boiling water. This should take between five and 10 minutes. When dried the microplates are immersed in a thionin solution made up as follows:

Thionin—1 gram
Carbolic acid—2½ grams
Distilled water—400 ml.

Filter, and add five per cent of glacial acetic acid. No preparatory fixation is necessary, as the acid in the solution prevents the agar from staining too deeply. Slides are stained for three minutes, then carefully washed, dried, and examined under the 16 mm. objective. The microscope should be so adjusted that the area of the field with this objective will be 2 mm². The technique described enables counts up to 50,000 molds and 1,000,000 yeasts per ml. to be obtained from 1.5 dilution.

COUNTING OF COLONIES

With the majority of samples analyzed, the counting of 20 fields on the microplate gives sufficient accuracy for routine work, where rapidity and convenience are more important than extreme accuracy. Tests, where various numbers of fields have been counted, have rarely shown any significant change through the counting of more than 20 fields. The case of low-count butter provides an exception; here it is advisable to increase the number to 40. Also should the yeast count exceed 50 colonies per field, the counting of 10 fields will suffice. After a rapid preliminary survey to determine the evenness of distribution of the colonies, 20 representative fields are counted, preferably with the aid of a mechanical stage. Counts on duplicate microplates are then averaged, and molds and yeasts per ml. of butter calculated from the formula.

$$\frac{A}{B} \times X \times Y \times Z = N$$

where A = number of colonies observed
B = number of fields counted
X = reciprocal of dilution
Y = reciprocal of quantity plated
Z = microscopic factor
N = number of molds (or yeasts) per ml.

For example, if the average of duplicate microplates showed 10 molds and 30 yeasts on 20 fields we would have

$$\begin{aligned} 10/20 \times 5 \times 5 \times 400 &= 5,000 \text{ molds per ml.} \\ 30/20 \times 5 \times 5 \times 400 &= 15,000 \text{ yeasts per ml.} \end{aligned}$$

This calculation can be greatly simplified by determining the number of molds (or yeasts) per field $\frac{(A)}{B}$ and multiplying by 10,000 ($X \times Y \times Z$) to obtain the number per ml. of butter (N). Where 40 fields are counted, the lower limit is $< 1/40 \times 5 \times 5 \times 400 = < 250$ per ml.

This lower limit could be reduced to < 125 ml. by employing an ocular which would give a field with a diameter of 2.25 mm. One was not available for the work reported here, but there seems no reason why it should not prove satisfactory.

Johns found that mold counts obtained by the Frost little-plate method were about twice as great as those obtained by the standard-plate method.

Shutt's¹⁸⁶ Method for Determining Molds in Butter. This procedure was submitted to the author in a personal communication. The apparatus required is the same as listed for determination of yeasts in butter.

Sampling. With a well-boiled and cooled butter iron remove a plug of butter from the print or solid and transfer the plug, less the top half-inch, to a sterile jar. If sample must be held it must be kept in cold storage not longer than 36 hours.

Method of Analysis. Place the water blanks and the samples of butter in a warming chamber at 41°C. (105.8°F.) until the water blanks are warm and the butter is melted. Shake the butter well.

Transfer 10 ml. of the melted butter, with a warmed pipette, to a 90-ml. water blank and shake 25 times. Make further dilutions if required.

Transfer one ml. of each dilution, including the original butter, to Petri plates and pour with acidified malt extract agar.

Incubate all plates at 25°C. (77°F.) for two to four days.

Count all mold colonies as follows:

Number of *Oidium* colonies

Number of *Penicillium* colonies

Number of miscellaneous mold colonies.

Mold Mycelia in Butter. Food-control officials have long wanted a method which would indicate whether or not butter had been made from cream which was unfit. Many believe that this need has been filled by a method which involves determining the number of mold mycelia in butter. An investigation by Vandaveer and Wildman²⁰¹ on the significance of mold mycelia in butter churned from cream of known histories resulted in the following conclusions: (1) Decomposition flavor characteristics occur when cream is exposed to adverse conditions of time, temperature, and sanitation. (2) The presence and growth of molds in cream are associated with the development of decomposition flavor characteristics. (3) There is a correlation between mold mycelia content of butter and the acidity of the cream from which it is churned; sweet cream or good sour cream produces a butter of a zero or a very low mycelia count, while butter made from high-acid cream almost invariably has a high mold-mycelia count. (4) A high mold-mycelia count in butter shows conclusively that decomposed or unfit cream was used.

Wildman's²³¹ Microscope Method for Estimation of Mold in Butter. Wildman's technique resulted from an extended study of the problem. In the first experiments the butter was heated and the fat removed by decantation. To the remaining curd and serum sufficient 50 per cent glycerol solution was added to bring the volume back to that of the original butter used, after which a drop of the thoroughly mixed sample was mounted on a Howard counting chamber and the mold filaments counted as in the Howard method for tomato products. Necessity of long manipulation to remove the fat was eliminated by use of gasoline. At this stage certain samples of butter showed numerous mold filaments in all fields. To reveal any significant differences between samples, it was necessary to dilute the serum-glycerol mixture with seven parts of glycerol solution. It was unnecessary to remove the fat in this case because the globules were so diluted that they did not interfere. Finally, a gum solution was substituted for the glycerol. Wildman stated the method as follows:

EQUIPMENT AND REAGENTS

- (a) Measuring spoon— $\frac{1}{4}$ teaspoon.
- (b) Pipette—10 ml.
- (c) Gum solution—Make up one liter of a .75 per cent solution of carob bean gum with two per cent of added formaldehyde as a preservative. Use the clear supernatant solution, free from cells, left when the cellular elements in the gum gradually settle out. (A similar solution made with gum tragacanth may also be used for this purpose.)

230. Clerkin. 1929. Dept. Agr. J. (Dublin) 28, 199-207.

231. Wildman. 1937. J. Assoc. Off. Agr. Chem. 20, 93-100.

PROCEDURE

Weigh out one gram of butter by means of the one-fourth teaspoon measure. Measure out seven ml. of hot gum solution and, with the spoon bottom side up over a 50 ml. beaker, pour two or three ml. of the hot solution over the spoon. (This quantity is usually sufficient to loosen the butter and cause it to slide into the beaker.) Use the remainder of the seven ml. of solution to rinse the remaining fat from the spoon.

Stir until the solution is well mixed and fat globules are .1-.2 mm. in diameter. The stirring necessary to obtain a uniform sample must be determined by experience.)

Mount a portion of the mixture on the mold-counting slide and estimate the mold by the Howard method. Report no field as positive unless the combined length of the two longest filaments exceeds one-sixth of the diameter of the field.

For applying this method to cream, Wildman first churned it, and used the above method. Since a small sample of butter is used, the question naturally arose as to whether a single sample could be representative of the total amount of butter in the churn. Investigation of this indicated that the results were close on various samples, indicating that molds were evenly distributed in a churn.

Wildman²³² later reported that a stain was not necessary for detecting presence of mold filaments when proper illumination was obtained. In certain cases addition of one or two drops of a five-per cent solution of crystal violet to the gum-butter mixture, if the butter is melted, was helpful. Wildman called attention to the possibility that carob bean gum and gum tragacanth might be impossible to secure. Study was being given to the possibility of using pectin and algin solutions but official recommendations were not made because further investigations were necessary. Prevention of mold growth in stored samples was prevented by a saturated atmosphere of formaldehyde. Disks of filter paper saturated with formaldehyde were fastened in the lids of the sample jars.

If mold counts are to be made on butter as an index of undesirable conditions in manufacture, much control work must be done to determine the incidence of these fungi in commercial butter. Wildman²³² examined 65 samples taken at random. These samples were said to represent an accurate cross section of the butter market. He also counted the molds in 53 samples that were taken from lots seized for mold or filth. It was found that the bulk of the seizure samples contained from 50 to 90 per cent while the bulk of the random samples varied from 0 to 30 per cent.

Mold Count Standards. If the laboratory examination of butter is to include examination for molds with approved or standard methods, some standards must be available with which to judge quality. Hood¹⁹⁵ suggested that pasteurized butter should contain less than 25,000 bacteria and less than a total of 50 molds and yeasts.

Sediment in Butter. This has become an important subject in view of the position taken by the United States Food and Drug Administration toward foreign matter in butter. Both cream and butter are being scru-

tinized carefully for such matter. Parfitt²³³ pointed out some of the difficulties when sediment tests are made on cream and butter. Such foreign matter in cream indicates carelessness on the part of the producer. Parfitt could find no relation between the amount or kind of sediment in butter and the number of living yeasts and molds.

The sediment test has been thoroughly investigated by a Research Committee of the American Butter Institute²³⁴ and found to be satisfactory for cream and butter. The American Butter Institute has adopted the Connecticut Official Milk Sediment Standards for interpreting results of sediment tests applied to cream and butter.

Parfitt's²³³ Method for Determining Sediment in Cream and Butter. *Using Lintine Disks*—Weigh into a 400-ml. beaker 100 gm. \pm .1 gm. of the butter to be examined. Add 200 ml. of .03 to .05 N. hydrochloric acid. Heat the mixture over a water bath to 74°C. (165.2°F.), stirring thoroughly to insure complete mixing. Run through a milk sediment tester. Rinse out the tester with at least 120 ml. of 83°C. (181.4°F.) filtered water. Mount and examine the soiled lintine disk.

Using Filter Papers (Horral)—Weigh into a 400-ml. beaker 100 gm. \pm .1 gm. of the butter to be examined. Add 150 ml. of .03 normal hydrochloric acid (3.2 ml. of 35-37 per cent hydrochloric acid diluted to 1 liter with distilled water) and place this mixture in an 83°C. water bath. Heat until butter is melted. Stir the mixture but once and let it stand until the milk fat rises. Place the filter paper (Max Dreverhoff No. 86, or equivalent) in a seven-cm. Buchner funnel containing a 50-mesh copper screen (diameter of which is slightly less than the series of holes in the funnel), seal the paper by suction, and warm the funnel with distilled water at 83°C. After sealing, pour the prepared samples of butter very slowly on to the paper, permitting the fat to pour on to the filter paper first. If the filter clogs, pour distilled water at about 83°C. slowly on the paper until it filters freely; repeat this if necessary until the sample is filtered, then wash the beaker, funnel, and paper free from fat using hot distilled water. With a pair of tweezers place the filter paper in a Petri dish, or similar container, to prevent contamination.

Greene's²³⁵ Method for Determination of Extraneous Material in Butter. Various types of foreign matter may reach butter if it is not carefully handled during manufacture. Greene (1935) devised a method which has been of value in detecting the presence of filth in form of insects and other extraneous materials in butter.

Method. Weigh out 100 grams of the butter from each sub-division in a 400-ml. beaker. To this add 150 to 200 ml. of borax solution made by dissolving 40 grams of borax in one liter of water (stronger alkaline solutions must not be used as they are destructive to hair). Heat on electric hot plate to boiling. Filter at once through a seven-cm. Buchner suction funnel equipped with a rapid filter paper, wash the paper with gasoline to remove any remaining grease and then with hot water. When a butter contains mold, either finely divided or in clumps, it may close the pores of the paper so that as many as 10 separate papers are required in extremely moldy butter to filter one sample.

After investigating brands of filter paper supplied by different dealers and manufacturers, the most efficient found was No. 86, seven cm., made by Max Dreverhoff and supplied by Heil Corp., 210 S. 4th St., St. Louis, Mo. As an aid in filtering, a circle of copper screen, 50 mesh, is cut about 6.5 cm. in diameter and fashioned to lie in the bottom of the funnel. The paper is then placed over this making sure that the paper and screen are centered to make a tight seal and not allow any material to pass under around the edges. The paper may be moistened with water to hold it in place before pouring the butter solution into the funnel.

233. Parfitt. 1937. Amer. J. Pub. Health 27, 341-345.

234. Parfitt (Chairman). 1938. J. Milk Tech. 1, 44-47; (Aug. 1937, issue of J. Dairy Science has the complete report).

235. Greene. 1935. Food Industries. Sept. 1935.

By the above described method, the curd is changed by the borax solution into a soluble caseinate and therefore all of it readily passes through, leaving no deposit on the filter paper. When mold is present in the butter, it is retained on the filter paper either in a finely divided condition or in large clumps which sometimes resemble undissolved curd, but if this material is scraped off, placed on a microscope slide with a drop of oil or glycerine, and pressed out quite thin, the mold filaments may be seen. An estimation is made of the total square area that would be occupied by the mold clumps if they were all moved in together. Search should be made of the sides of the Buchner funnel to insure that no mold, insects, or other foreign material has been retained there. In connection with distinguishing the material as mold, the analyst must bear in mind the distinguishing characteristics between mold and paper since occasionally fragments of the latter have been found.

Attention is called to the fact that in those cases where a slimy residue is recovered on the filter papers which is suggestive of mold, it is our practice to always verify this by making examinations of a small portion of the substance under a compound microscope. This caution is observed because it has sometimes been found that such residues are in the main composed of curd with but little mold present. The reason for this variation in different samples we have not yet been able to answer to our full satisfaction, but the fact remains and this method of verification has been followed to avoid erring on such a condition.

The filter paper is examined with a wide-field binocular microscope, with lenses giving a magnification of approximately 15-20 X. A lower magnification may be used to find larvae but the 20 X is recommended for other material. Hairs, fragments of insects, and other contaminants except mold are removed with a needle, placed in a drop of glycerine on a slide, and covered with a cover glass for further examination.

Margarine. This is not strictly a dairy product, but on account of its close relation to butter and the fact certain dairy products are used in its manufacture, brief mention may be made of it.

Two quite distinct types of margarine are made in America; one is prepared from animal fats and perhaps is more commonly known as "oleo" while the other is prepared from certain vegetable oils and known as "nut margarine." These artificial butter substitutes are prepared in somewhat the same manner. They consist of soft oils and hard oils which are crystallized after careful purification. These oils are mixed in the proper proportions in churns where they are churned from 15 to 20 minutes. Longer churning gives a higher grade product. After churning, the batch is crystallized by means of cold-water spray or other methods, and conducted to vats where it is allowed to stand at a constant temperature to ripen. This ripening produces a better flavor. When the flavor has been sufficiently developed in the ripening process, the margarine is thoroughly worked on kneading tables to adjust the water content and also bleach the product. It is sold in packages and in bulk.

That rancidity of margarine is due to microorganisms seems very probable (Jacobson²³⁶). The use of rancid cocoanut oil may cause rancid margarine, but this is not the sole explanation. If the oil or margarine contains small amounts of water, molds may develop and bring about undesirable changes. *Penicillium glaucum* has been found in rancid margarine, also *Aspergillus* sp. Margarine keeps when sufficient salt is used to make a brine in each water droplet. Other preservatives will also cause

the margarine to keep. Stokoe²³⁷ did not believe that bacteria played any role in rancidity of water-free fats. A culture of an organism from rancid margarine was inoculated into many fats and oils. After 14 days, there was only the slightest increase in free fatty acids. Stokoe divided rancidity of margarine into three groups:

1. Fats becoming rancid with tallowy flavor and odor without change of color caused, like tallowiness of butter, by an oxidation process. According to the views of the English chemists, the glycerin which is first split off is oxidized to glyceric acid.

2. Rancid fat with aromatic but not disagreeable odor but with an offensive taste. These occur only in margarine that contains cocoa fat or palm oil, and consequently, is not observed in butter. This type of rancidity is caused by *Penicillium glaucum*. Ketones are the volatile substances produced.

3. Rancid fats with a change in the color and small change in the odor and flavor. The changes observed are (1) gray or blue-black coloring caused by *Aspergillus* species; (2) red coloration by *Serratia marcescens* (*Bacillus prodigiosus*.)

Fresh, well-prepared margarine, according to Hoffmann, contains principally lactic acid bacteria of the diplococcus type, since milk is used in its preparation. If milk which has become too sour is used, the long-chain streptococci will predominate. This prevents the production of the delicate butter flavor. The more water present in the margarine, the less the keeping qualities.

Great variety was found by Horovitz-Vlasova *et al.*²³⁸ in the bacterial flora of margarine in addition to the acid-forming organisms introduced in the milk. There are bacteria and fungi coming from the air or the wrapper and capable of causing spoilage. Scrupulous cleanliness in manufacturing is essential to good keeping quality in margarine; experiments show that, like butter, it is stable for weeks or even months to pure cultures of the lactic organisms but quickly becomes rancid if contaminated with *Penicillium*, *Oidium*, or *Bacillus fluorescens liquefaciens* since neither prior acidification, salting, nor cold storage is sufficient to stop the growth of these fungi. Oxidative spoilage, causing a tallowy consistency, is accelerated by air, light, and moisture; hence margarine should be well pressed, wrapped in good parchment paper, packed in fungus-free tubes, and kept in a scrupulously clean room. Margarine made with soybean milk instead of cow milk shows the same behavior. Diacetyl is recommended for imparting butter aroma.

Margarine should be free from pathogenic bacteria since it is made from safe raw materials. No tuberculosis organisms in 150 samples of margarine were found by Eber.²³⁹ Presence of tubercle bacilli in this product would not be probable.

A fungus causing spoilage of margarine, to which the name of *Marginomycetes bubaki* was given, was reported by Laxa.²⁴⁰ This fungus caused greenish-black spots in the margarine. The fungus could be controlled by more careful methods of manufacture.

CHAPTER 9

MICROBIOLOGY OF CHEESE

In the United States the term "cheese" unqualified is generally understood to mean Cheddar cheese, American cheese or American Cheddar cheese. Many other kinds are known, some of which, formerly imported, are now made in large amounts in the United States. According to Doane and Lawson,¹ there are probably 18 distinct varieties of cheese known under some 400 different names. These are usually of local origin and bear names of towns or communities.

Cheese may also be classified in other ways. Rennin curd cheeses are made from curd secured by the action of rennin while acid curd cheeses are secured by the artificial or natural souring of milk. Those who are interested in a discussion of the hundreds of varieties of cheese may consult the bulletin by Doane and Lawson,¹ who remarked that attempts to classify cheeses have usually been unsatisfactory. Some of the international problems of cheese nomenclature have been discussed by Swaving² and Porcher.³

The Food and Drug Administration in accordance with provisions in the Food, Drug, and Cosmetic Act of 1938⁴ defined Cheddar cheese as cheese made from cow's milk containing not more than 39 per cent of moisture, and its solids containing not less than 50 per cent of milk fat. The rest of the definition concerns its method of manufacture.

Pasteurization of Milk for Cheese Making. Differences of opinion exist over the question whether cheese can be made from pasteurized milk. Pasteurization should have the same functions here that it has for other dairy products. It should improve the quality of cheese by eliminating defects caused by undesirable microorganisms in raw milk. Furthermore it should make cheese safer by destroying pathogenic bacteria in the milk, should they be present. Cheese from raw milk, in Lane and Hammer's⁵ experiments, was better in both quality and texture. Their work involved cheese made from raw milk, from pasteurized milk, and from a mixed milk composed of 90 per cent pasteurized and 10 per cent raw. Raw-milk cheese had good flavor while pasteurized-milk cheese had a tough, rubbery texture. Some of the cheeses in their experiments were inoculated with *Lactobacillus casei*, certain strains of which, when added to pasteurized milk used for making Cheddar cheese, had a desirable effect on protein decomposition, flavor, and uniformity of cheese. For Swiss cheese, Babel and Hammer⁶ found it desirable to add propionic acid-forming bacteria to pasteurized milk to secure good flavor and eye formation. Price⁷ believed that all

of the more common types of cheese made in the United States could be made from pasteurized milk with the exception of Swiss.

Pasteurization in Phillips' ⁸ experiments improved the quality of cheese made from poor milk but had little effect on cheese made from good milk. Pasteurizing gassy milk at 80°C.(176°F.) produced better cheese than if raw milk had been used. Here is an instance when undesirable bacteria were destroyed. Murray ⁹ had previously reported the same experience.

The other aspects of this subject concern health hazards of cheese made from raw milk. While it is probably not as true today as formerly, raw milk may contain *Mycobacterium tuberculosis*, an organism which may live for many months in cheese. Other pathogenic bacteria, such as *Eberthella typhosa*,¹⁰ have also been found. The fact that pasteurization makes cheese safe would be a strong argument in its favor. *Standards of Identity for Cheddar Cheese* ⁴ states that milk from which it is made *may* be pasteurized. This important public-health effort is left as optional, even though epidemics of typhoid fever and undulant fever have been traced indisputably to cheese.

Phosphatase Test Applied to Cheese. This test for adequate pasteurization was applied to cheese by Scharer.¹¹ On account of the acidity and high protein content of cheese, the sample should be neutralized and diluted as follows: Triturate 20 gm. of cheese in 20 ml. of the buffer and 20 ml. of water. Use a one-ml. portion and proceed as for milk. Scharer detected the enzyme after 18 months' storage with undiminished activity in cheese made from raw milk. It was absent in cheese made from milk pasteurized by both "holder" and high temperature-short time methods. Pasteurized processed, packaged cheese was, in general, negative for phosphatase. Other types of cheese were frequently positive. Presence of the enzyme phosphatase in cheese was believed by Sharer to indicate use of raw or improperly pasteurized milk or cream.

Cheddar Cheese. This cheese derives its name from the village in England where it was first made. In the United States it is called American cheese and is probably the most popular variety. More has been written about the role of microorganisms in preparation of this cheese than any other variety.

Ripening of Cheddar Cheese. By means of this process Cheddar cheese acquires those characteristics by which it is so well known. The most important agents are bacteria with, perhaps, milk enzymes having small part. It is a complicated process, as Davis ¹² has shown. Some of the early investigators attributed a role in the ripening process to enzymes from the cow also.

Many investigations have been carried out to determine the influence of various factors on the activities of bacteria. The bacteriological aspects

of the subject were reviewed by Hucker.¹³ Several different explanations have been given to explain the appearance of the characteristic flavor. Baier¹⁴ did not connect any specific bacterium with cheese ripening, while Orla-Jensen¹⁵ attributed it to the action of the enzyme casease, very similar to tryptase. Studies by Shirokih¹⁶ on products formed by bacteria in milk caused him to believe that the peptonizing bacteria played an important role in cheese ripening. One does not read the literature of the subject long before encountering the name of Freudenreich.¹⁷ From extensive experiments reported in 1897, he stated that lactic acid-producing organisms were important, for cheese would not ripen when liquefying bacteria were used alone. Weigmann¹⁸ denied the statements of Freudenreich; he did admit, however, that they played an indirect role in providing an acid medium. Freudenreich¹⁹ replied to Weigmann's criticisms and explained the controversy on the ground that he had used hard cheese, while Weigmann used soft cheese. Weigmann reported more data which seemed to show that cheese ripening was a symbiotic phenomenon in which a number of different types of bacteria played a role. This opinion was based on data secured from experiments with Titsler cheese. Harrison²⁰ and Chodat and Hofman-Bang,²¹ in general, believed that lactic acid bacteria were of indirect importance, and that they did not have the importance with Freudenreich attributed to them. The latter believed that ripening was due to the digestive action of rennin in the presence of acid.

Harding²² also carried out some experiments to determine whether lactic acid bacteria played a role in ripening of Cheddar cheese. In the introduction of his bulletin, brief explanations are given concerning three theories of cheese ripening: (1) that ripening is due, mainly, if not entirely, to lactic acid bacteria; (2) that ripening is brought about by liquefying bacteria; and (3) that the breaking down of the casein is largely due to the enzymes naturally present in milk. In factory milk lactic acid bacteria were said to be always present, and at the time of souring commonly make up more than 95 per cent of the total number. The rapid development of the lactic acid bacteria checks the growth of other species, owing to the conversion of milk sugar into lactic acid. The action of this acid has been found in practice, and shown experimentally, to hasten the curdling action of rennin. Investigations have shown that lactic acid combines with paracasein to form two salts, one the unsaturated paracasein monolactate, insoluble in water but soluble in dilute salt solutions, and the other the saturated paracasein di-lactate, insoluble in both water and dilute salt solutions. That paracasein monolactate was formed in cheese curd by lactic acid bacteria was shown experimentally as follows:

Fresh milk was curdled by rennin in the presence of ether to prevent bacterial growth, and the curd was washed with water to remove the greater part of the sugar. After sterilization, portions of the curd were inoculated with lactic acid bacteria, with and without the addition of sugar. Without the addition of sugar, only very small quantities of paracasein monolactate were formed, while with the addition of sugar considerable amounts were produced. In normal cheese during the first week after it is made, it was stated that from one-half to three-fourths of the nitrogen was found in the form of paracasein monolactate. In forming the amount of monolactate ordinarily present, the bacteria use up an amount of sugar equal to two to four per cent of the weight of the cheese. The presence of the monolactate was considered essential to the digestive action of the rennin enzyme. The action of rennin was not believed to extend much beyond the formation of peptones, leaving the formation of the simpler nitrogenous compounds characteristic of a ripened cheese to be explained in some other manner.

The statements above on the ripening of cheese are based almost entirely on experiments with Cheddar cheese. Some investigators have studied the types of microorganisms in cheese after its preparation. Harding and Prucha²³ isolated and studied more than 300 pure cultures of bacteria from Cheddar cheese by means of the group number on the descriptive chart of the Society of American Bacteriologists. When these strains were studied, they fell into 33 groups. *Lactobacillus lactis acidii* made up over 99 per cent of the total bacterial count. Hastings, Evans, and Hart²⁴ conducted a similar investigation. They stated that *Lactobacillus lactis acidii* was very important and summed up the role of these microorganisms as follows:

1. They favor the curdling process.
2. They favor the expulsion of whey.
3. They permit the fusing of curd particles.
4. They activate the pepsin in the rennin extract.
5. They have a protective action against the putrefactive bacteria.

They stated that development of *Lactobacillus lactis acidii* was followed by the growth of members of the *Lactobacillus bulgaricus* group which reach numbers comparable with those of the first group within the first month of ripening. Since they develop after the sugar has been fermented, they must have some other source of carbon and of energy than milk sugar. Another interesting observation was that enzymes play quite a role in cheese ripening since acid was formed in the absence of living cells. These authors believed that the constant presence in large numbers is the only certain proof that a group of organisms is important in cheese ripening.

Protein decomposition is important in cheese ripening because the products formed are responsible for cheese flavor. Raw-milk cheese, according to Lane and Hammer,²⁵ undergoes a more rapid and extensive decomposition than cheese made from pasteurized milk. After two months flavor

scores were higher in the cheese from raw milk while that made from pasteurized milk was characterized by lack of flavor and a tough, rubbery body. Sherwood²⁶ also investigated this question to determine whether pasteurization at various temperatures was sufficient to modify proteolytic action of enzymes when bacterial action was inhibited by two per cent of chloroform. Pasteurization seemed to reduce proteolytic activity of both enzymes and bacteria.

Use of pure-culture inoculation of Cheddar cheese gave inconsistent results in the hands of Harris and Hammer.²⁷ Thirty-four cultures of *Micrococcus* originally isolated from Cheddar cheese were used. Strains of micrococci apparently belonging to the same species differed in their effects on flavor. When used in small numbers, certain strains of propionic acid bacteria improved the flavor of pasteurized milk Cheddar cheese, while others had no definite effect; when used in large numbers all the strains improved the flavor, and some of them produced a distinct sweet flavor somewhat resembling that of Swiss cheese. It might be possible to improve the flavor of pasteurized-milk Cheddar cheese by adding to the milk various organisms other than the usual cheese cultures.

Off-Flavors in Cheddar Cheese. These may be due to development of various microorganisms. Whitehead's²⁸ experiments showed that representative strains of organisms of the coliform group had a deleterious effect on the flavor of Cheddar cheese when added to the milk just before the start of the manufacturing process. Even when present in large numbers they did not produce gas holes if an active culture of lactic streptococci was used as a "starter." This indicates that metabolism was so modified by association with the starter that while they grew they produced little or no gas. In this study they had no influence on the texture of the cheese, nor did they appreciably affect the production of acid by the starter in the milk or curd. Since they did not cause decolorization of annatto in a colored cheese, it did not seem likely that they were responsible for mottling in cheese. These organisms may come from a variety of sources. Albini²⁹ examined several kinds of cheese for the presence of bacteria belonging to the coli-aerogenes group, with a view to determining the sources and degree of impurity. His investigations led to the conclusions that in most cases the organisms are not in the milk from which the cheeses are made but are introduced in the process of manufacture. Those cheeses which in the process are subjected to the prolonged action of salt contain far fewer of these organisms than others. Albini utters a plea for better surveillance of cheese dairies and for wider application of more modern methods of manufacture. The grading of all cheeses by the Dominion of Canada Department of Agriculture during 1930 showed about one per cent to be rancid. This condition was reproduced by Hood and White³⁰ by adding undesirable bacteria to the cheese milk. Milk containing manure, dust, or

feed may contain many butyric acid or rancidity producing bacteria. Low-grade milk was found to be the cause of much rancidity.

The development of acidities greater than pH 5 at four days after making the cheese, according to Phillips and Price,³¹ may contribute to the production of bitter flavor. Acid development in the bitter cheese was much more rapid than in the low-acid groups, but slower than in the high-acid group. Excess acidity in the curd may be brought about by use of a very active starter, and by using milk in which too much acid has been permitted to develop. Differences in moisture content in curd has no relation to bitterness. Limiting of acidity during the curd-making operations is recommended as an aid in improving cheese quality.

Canned Cheese. Rapid molding of cheese in some seasons and the desire to hold it over long periods prompted attempts to can it. Pernot³² was among the first, if not the first, to successfully hold cheese in cans. He shipped cans of cheese long distances by sea and land and found it able to stand up. His cheese "cured" in the cans. Rogers³³ described a method of canning Cheddar cheese, the essential feature of which method is a valve which permits escape of gases formed during ripening without allowing ingress of air. The cheese ripens normally without loss of moisture, formation of rind, or growth of mold. The increased cost of cheese in this package is largely offset by elimination of loss through evaporation, necessity for paraffining, and care of the cheese in the curing room. Use of this can means that some of the ripening process occurs in the can, which makes it necessary to have a ventilation valve.

Bacteriophage in Cheese Making. Most cheese makers have culture problems, explanations for which have not been available. Among them is slow acid formation, the solution of which has usually been to secure new cultures. Cheese makers in New Zealand who use a single strain of bacteria have found some of them to be contaminated with bacteriophage which destroys all of the bacteria. Whitehead and Hunter³⁴ believed bacteriophage to be of common occurrence under dairy-manufacturing conditions. Bacteriophages which they isolated showed a strain specificity but some races attacked as many as four strains. They also observed that chlorine and permanganate destroyed the phage. Whitehead and Hunter had previously attributed failure of single-culture starter in Cheddar cheese manufacture to bacteriophage in air-borne, fine whey particles. Special rooms had to be used where air-borne infection could not occur. Johns³⁵ demonstrated bacteriophage in a starter in Canada. It attacked all of 10 bacterial species in the starter. Thorough sterilization and cleaning of equipment helped. Johns was able to reproduce the trouble experimentally. Strict sanitation in the factory and proper handling of starters seem to be involved in prevention of phage troubles.

Cottage Cheese. This is a simple cheese widely made in rural districts of the United States. It varies widely in flavor and texture because it is made in small batches and because of varying tastes among consumers. Starter may be added to assist in curdling. The curdled milk is heated to about 37.8°C. (100°F.) and allowed to remain at this temperature for 30 minutes after which the whey is drained. The curd may be washed, salted, and used as it is or after it has been mixed with cream. Microbiology of cottage cheese follows quite closely that of the milk from which it is made and the starter which may be used. Diehm³⁶ analyzed some 10 samples purchased at different places. The greatest number of colonies appeared on plates made from a sample which had been stored uniced. The smallest number came from an iced sample. More colonies developed at 37°C. (98.6°F.) than at room temperature. *Streptococcus lactis* was the pre-dominating organism. *Oospora lactis* was also present. Ellenberger³⁷ found storage conditions to be important in keeping cottage cheese of high quality.

Blue or Blue-Veined Cheeses. These are cheeses which are in general ripened by the action of molds belonging to the genus *Penicillium*. The most common and probably the oldest is Roquefort cheese originally prepared in France from goat's or sheep's milk. It differs from Camembert cheese in being ripened throughout by the mold *Penicillium roquefortii*. The air spaces are surrounded with vegetation of this mold which gives Roquefort cheese its blue-green appearance. This mold digests the curd quite completely. This cheese is made by pressing alternate layers of curd and mold powder into five- or six-pound bricks, punching them full of holes to allow entrance of air, and allowing them to ripen under controlled atmospheric conditions. The inoculum of *Penicillium roquefortii* may be gotten into the curd in different ways. Hussong and Hammer³⁸ grew the mold on bread which was ground into a powder when dry. Only a small amount of this powder was found to be necessary by Lane and Hammer³⁹; .01 per cent produced satisfactory mold growth in cheese. The inoculum was best mixed with the curd to secure good distribution. Lane and Hammer found that homogenized milk offered some advantages, for the volatile acidities and acid numbers on cheese fat were considerably greater in cheese made from such milk. Attempts by Hammer and Bryant⁴⁰ to find the chemical substance which is responsible for the flavor of Roquefort cheese indicated that it might be methyl-n-amyl ketone formed by the mold from caprylic acid.

Thom⁴¹ stated cheeses of the same quality were made in Europe from mixtures of cow's and sheep's milk or cow's milk alone. He noticed remarkable uniformity in cultures from the interior of cheeses. Usually a single species of *Penicillium* existed along with a few typical lactic acid-

producing species. By means of the mold, then referred to as the Roquefort *Penicillium*, Thom was able to make good cheese with cow's milk. Thom, Currie, and Matheson⁴² later enlarged on this and described in more detail preparation of this type of cheese in America. Salt was observed to inhibit microorganisms which were not desired, such as *Oidium lactis*. Thom's observations on the function of *Penicillium roquefortii* were in general confirmed by Evans⁴³ who found *Streptococcus lactis* and *Penicillium roquefortii* to be essential for making Roquefort cheese. The former decomposed the lactose to produce the acidity necessary for cheese making. After two or three weeks these organisms disappear. The flora then consists mainly of cheese streptococci and *Lactobacillus bulgaricum*, organisms which are found in all kinds of cheeses. These bacteria play no role in ripening of Roquefort cheese. The mold is most important. Currie⁴⁴ found the mold to be well provided with enzymes for producing compounds concerned with flavor. While most investigators gave the mold most credit for the proper decompositions, Dvorak⁴⁵ believed that a symbiosis of the lactic acid-producing bacteria and mold was involved.

Blue-veined cheeses are subject to deterioration; Lane and Hammer³⁹ mentioned two types, lack of development of good flavor and black discoloration. The former was said to be due to lack of development of the mold. One type of black discoloration was attributed by Bryant and Hammer⁴⁶ to growth of *Hormodendron olivaceum*, particularly in punch holes and cracks in the surface. Gas formation was said to be of little importance in blue cheeses. Trials with a culture of *Aerobacter aerogenes* showed that inoculation of milk which resulted in very gassy Cheddar cheese caused no, or only insignificant, numbers of gas holes in blue cheese. Production of good blue cheese depends on use of a good strain of *Penicillium roquefortii* and elimination of contamination microorganisms which might bring about abnormal protein decomposition.

Camembert Cheese. This cheese originated in the village in France from which it derives its name. It is a soft cheese made with rennin from cow's milk. Camembert is made in smaller units than other cheeses and is provided with a hard exterior, or rind of hard cheese covered with molds, and a soft interior. *Penicillium camemberti* along with bacteria and molds is the important fungus. Early bacteriological work on Camembert cheese in the United States was carried out by Conn, Thom, Bosworth, Stocking, and Issajeff⁴⁷ and Thom.⁴⁸ The first object is to secure good production of lactic acid, during which lactic acid-producing bacteria predominate. Following this period, lactic acid concentration decreases and the mold makes itself evident. In three to five weeks, much of the curd has been decomposed with appearance of characteristic odor and

flavor. Thom stated that *Penicillium camemberti* was the only mold studied up to that time which could produce the desired changes in curd soured by lactic acid without producing objectionable flavor. In spite of this Thom did not exclude *Oidium lactis* or bacteria from having a part. Other fungi might produce undesirable flavor.

Other than the necessary mold, *Penicillium camemberti*, many bacteria and yeasts are present in Camembert cheese. Esten and Mason⁴⁹ stated that 99 per cent or more of the bacteria in the interior of Camembert cheese were of the lactic acid-producing type. That yeast forms an important part of the surface flora of Camembert cheese is indicated by results of investigations by Guittonneau, Keiling, and de Laval.⁵⁰ Among the various species isolated were those which fermented lactose with production of alcohol and esters. Many of the yeasts which were isolated are peculiarly fitted to grow in symbiosis with lactic acid-producing bacteria and to constitute an important part of the surface flora. The more practical problems relating to manufacture of Camembert cheese were studied by Thom.⁵¹

Brick Cheese. This is an American cheese the real origin of which is not known. Doane and Lawson¹ stated that it is about half way between Limburger and Emmentaler with a strong sweetish taste, elastic texture, and many round eyes or holes. Brick cheese is a rennin curd cheese. Varied microorganisms were found by Filipovic⁵² in it. Anaerobes outnumbered aerobes. Frazier and his students have studied American brick cheese. They made it by the conventional method with *Streptococcus lactis* and *Streptococcus thermophilus* starters used singly and in different combinations. When used alone neither of the starters produced brick cheese of satisfactory quality. *Streptococcus lactis* starter produced a cheese with a sour flavor and a short, crumbly body, while *Streptococcus thermophilus* produced a fermented flavor with open texture. From results of investigations of Garey, Foster, and Frazier⁵³ good brick cheese depends on proper amounts of starter and proper processing of the cheese during manufacture.

Swiss or Emmentaler Cheese. This is a hard, dry cheese with a mild flavor and many large holes throughout the cheese mass. It is now widely manufactured in the northern United States. It is well known that as good cheese of this type can be manufactured in America as abroad. Von Freudenreich⁵⁴ observed many lactic acid-producing bacteria with few liquefying forms. At this time nothing was known as to the origin of the holes in Swiss cheese. Jensen⁵⁵ attributed them to carbon dioxide formed by the lactic acid bacteria under certain conditions. Von Freudenreich and Jensen,⁵⁶ however, later showed that calcium lactate was fermented

by certain bacteria to propionic acid and carbon dioxide. The bacteria were described. They were found only in small numbers in Swiss cheese examined by Eldredge and Rogers.⁵⁷ Three morphological groups of bacteria were arranged. They stated that the essential bacteria of Emmentaler cheese were evidently not ubiquitous. Sherman⁵⁸ isolated *Bacterium acidi-propionici* (d) as the essential bacterium for production of eyes and characteristic flavor of Swiss cheese. This was proved in factory experiments.

Some European workers found that *Lactobacillus bulgaricus* produced good commercial Swiss cheese, an observation not concurred in by Sherman.⁵⁹ Matheson⁶⁰ used it in starters and secured good eye-formation and flavor. So-called "stinker cheeses" were suppressed. Sherman seemed to confirm this statement that undesirable fermentations could be suppressed. Frazier, Burkey, Matheson, and Watson⁶¹ showed that use of starters containing *Streptococcus thermophilus* in addition to the usual *Lactobacillus casei* or *Lactobacillus bulgaricus* bettered the quality, with marked improvement in eye-formation, texture, and flavor. There was, however, a tendency to produce more checking and gas. Three strains of *Streptococcus thermophilus* produced different results in cheese. Use of pure cultures of *Streptococcus thermophilus* in cheese is recommended as part of the pure culture method. What happens to these bacteria in the cheese is largely determined by the temperature at which the cheese is held. Frazier, Burkey, Boyer, Somers, and Matheson⁶² stated that the temperature at dipping 50 to 51°C. (122 to 123.8°F.) prevented increase in numbers of bacteria for several hours, although the pH decreased rapidly. *Streptococcus thermophilus* increased in numbers within three or four hours after dipping. Coliform bacteria may grow in the press and cause gasiness. Results of further investigations by Frazier, Johnson, Evans, and Ramsdell⁶³ on manufacture of Swiss cheese under factory conditions indicated a good product could be secured with a *Lactobacillus helveticus* starter in combination with *Streptococcus thermophilus*.

Eighteen strains of propionic acid-forming bacteria were used by Babel and Hammer⁶ in manufacture of Swiss-type cheese from pasteurized milk. Several of the cultures were consistent in flavor production while others were variable. In general, cultures which developed actively gave the best flavors. None of the cultures consistently gave good eyes. In several series the control cheeses, made without added propionic acid bacteria, developed a good flavor; propionic acid-producing bacteria were found in these control cheeses in large numbers. The commonest defect in the cheese was poor eye-formation. Large numbers of coliform bacteria were more objectionable from the standpoint of flavor since eyes were small

and numerous. Anaerobic sporeforming bacteria produced bad flavors and odors, that of butyric acid being conspicuous.

Gas Formation in Swiss Cheese. Formation of gas in Swiss cheese has been found by Weiser⁶⁴ to be due to lactose fermenting yeasts and facultative anaerobic bacteria of the *Clostridium perfringens* group. Accompanying formation of gas was lack of characteristic eye-formation, poor body, bitter flavor, and sometimes off-odor. Hostettler and Sahle⁶⁵ attributed this defect to coliform bacteria. A nonpathogenic strain of *Clostridium welchii* was isolated as the cause of this defect by Albus.⁶⁶

Limburger (Limburg) Cheese. This cheese also derives its name from a village in which it was marketed. It is known as Limburg or Limburger, either name being accepted. It is a rennin cheese made from cow's milk, praised by many and condemned by as many more. While earlier dairy bacteriologists studied the microorganisms on cheese of this type, it remained for Wolff⁶⁷ to initiate fundamental investigations at the dairy research institute at Kiel, which finally resulted in isolation of an organism, *Bacterium denigrans*, which was believed to be the special bacterium for making Limburger type cheese. Weigmann⁶⁸ later renamed the organism *Bacterium linens*, under which name it is known today although it has many more characteristics of members of the genus *Corynebacterium*. Wolff's work revealed the fact that better ripening of Limburger cheese resulted when a lemon-yellow, short rod was used along with *Bacterium linens*. Steinfatt⁶⁹ confirmed Wolff's work in fine manner and published results to show that *Bacterium linens* should probably be classed with *Corynebacterium*. He also showed the relationship which other lactobacilli may have to manufacture of Limburger cheese along with *Bacterium linens* and to formation of good flavor and aroma.

Limburger cheese in the past has been generally made from raw milk. Use of pasteurized milk introduced new problems. Yale,⁷⁰ however, found that Limburger cheese of good quality could be made from pasteurized milk if proper manufacturing methods are followed. Milk pasteurized at 62.8°C. (145°F.) yielded good cheese. Kelly⁷¹ observed a definite sequence with advance of the ripening period. Budding yeast cells appeared after two or three days, becoming abundant in four to five days when the surface became slimy. Uniform distribution of the organisms in the slime over the surface was accomplished by rubbing the cheeses with the hands. Short slender rods (*Bacterium linens*) appeared about the sixth or seventh day, rapidly increased in numbers, and were uniformly distributed over the surface about the eighth day. Undoubtedly these organisms are responsible for the reddish color which appears on the cheese at this time. The slime on the surface also became heavier or thicker at this stage. Yeast

cells decreased in size from the 10th to the 18th day and finally disappeared entirely. It is believed that other types of organisms, while present from time to time, do not have any important part in the ripening of Limburger cheese.

Processed Cheese. The advent of certain types of cheese which may be quickly characterized as loaf cheese, into the American market has introduced pasteurization of cheese. The cheese is allowed to ripen naturally and is pasteurized just before it is placed on the market. This process gives the advantage of blending and thus an improvement or equalization of flavor and quality. Robinson,⁷² who has discussed this question, stated that the keeping quality was also lengthened. To prove this, Robinson stored equal portions of pasteurized and unpasteurized cheese in a 37°C.(98.6°F.) incubator. After 20 days they were examined. All of the unpasteurized cheeses except one were swelled and spongy in texture. The pasteurized cheeses were in good condition. The methods of carrying out the pasteurization need not be reviewed here, except to state that the cheese is ground, heated in a jacketed container with agitation, and then filled into the container. Different cheeses may be pasteurized; different temperatures are used, however.

Defective processed cheese having a bleached appearance, crumbly texture, and a penetrating putrefactive odor caused by a *Clostridium coagulans*-like organism was studied by Griffiths.⁷³ This organism was believed to have come from milk of low quality.

One possible defect of processed cheese is gas formation resulting from development of microorganisms originating in the raw milk. Palmer and Sly⁷⁴ described the gas holes as generally in the form of slits in the cheese which becomes soft and spongy. In some cases the package may be distended. Palmer and Sly believed that proper processing temperatures were the best methods of preventing the defect. A minimum temperature of 73.9°C.(165°F.) was considered to be necessary for Cheddar cheese. The critical processing temperature was said to be 60 to 68.3°C.(140 to 155°F.). Below this temperature microorganisms causing spoilage can survive. Presence of .25 per cent of potassium nitrate seemed to inhibit gas formation. Palmer and Sly did not study the microorganisms involved. Albus and Ayers⁷⁵ stated that washing of pimientos to remove fermentable sugars, would prevent gas formation in processed cheese to which they had been added. Anaerobic bacteria have also caused gaseous spoilage of cheese. Csiszar⁷⁶ found that spores of *Clostridium sporogenes*, *Clostridium putrificum*, and *Bacillus saccharobutyricus* were destroyed only by temperatures which were too high to make a satisfactory product.

Rusty spots on Cheddar cheese are caused by chromogenic varieties of at least two distinct varieties of lactobacilli, *Lactobacillus plantarum* var. *rudensis* and *Lactobacillus brevis* var. *rudensis*, according to Pederson and

Breed.⁷⁷ They stated that these organisms were commonly present in the nonchromogenic form. The conditions under which pigment is formed are unknown. *Propionibacterium rubrum* van Niel was the cause of similar defect, according to Lubow.⁷⁸

Rancidity of Cheddar Cheese. A small percentage of cheese in Canada was found to be rancid or slightly so by the Department of Agriculture. Hood and White³⁰ reproduced the defect by addition of certain bacteria to the milk from which the cheese was made. These bacteria were isolated from poor-quality milk, improperly sterilized equipment, poor starters, bad water, and from factories in poor sanitary condition. Most rancid cheeses were traced to such factories.

Swelling of Emmentaler Cheese. Following introduction of Emmentaler cheese into the curing room or salt bath, an undesirable fermentation accompanied by gas formation may take place. Protuberances and crevices may form on the surface. Hostettler, Binz, and Sahle⁷⁹ found *Escherichia coli*, *Aerobacter aerogenes*, and *Bacillus casei delta* (Freudenreich) to be the cause. To prevent the defect, use of a strong, acid-producing rennet starter was recommended. Whitehead⁸⁰ observed that coliform bacteria even in large numbers formed no gas in Cheddar cheese if an active culture of streptococci was used as a starter. Coliform bacteria did have a deleterious effect on flavor.

Mold Growth on Cheese. Control of mold growth on foods has always been a problem. It has stimulated various investigators to seek a harmless substance which could be used for preventing development of molds. Results of experiments with certain fatty acids by Hoffman, Schweitzer, and Dalby⁸¹ showed that some were fungistatic. Among these propionic acid has received considerable study and has been shown to be valuable for control of molds in several different foods. Miller,⁸² Irvine and Sproule,⁸³ and John⁸⁴ all found propionic acid, or its soluble salts, to be quite inimical to molds on cheese. In Miller's experiments immersion of cuts of cheese in eight-per cent solutions of propionic acid increased the mold-free life of the cheese at 15.6°C. (60°F.) from the usual three to five days to 12 to 38 days, depending on the cheese and the method of treatment. Solutions of 14 to 16 per cent of the calcium or sodium salt were required to produce the same effect. Strong solutions of propionic acid up to 40 per cent failed to completely eliminate molds. Propionic acid is not, therefore, a germicide but an antiseptic or fungistat. Quite similar results were secured by Irvine and Sproule, who finally recommended a mixture of 10 per cent calcium propionate and 10 per cent propionic acid in the ratio of five to one. Mold inhibitive properties of propionic acid when

added to milk or cream or when used as a dip for parchment butter wrappers and for cheese were observed by Willingham.^{84a} It was ineffective when added to the exterior of cottage cheese; when mixed with the cheese it was effective. Propionic acid and its salts imparted a slight odor and flavor to dairy products but this was not objectionable.

According to Smith^{84b} ultraviolet light failed to control mold growth on cheese. He used a 15-Watt low-pressure burner emitting in 2500-2600 Å region. Irradiation of cheese immediately before paraffining, did not eradicate mold. The thickness of coating materials on cheese was found to greatly reduce penetrating power of the rays.

METHODS FOR MICROBIOLOGICAL EXAMINATION OF CHEESE

Methods for microbiological examination of cheese are not unlike those used for other dairy products after the cheese has been prepared for culturing. The first task is to secure a representative sample and prepare it for analysis. In the past this latter problem was solved by grinding it in a sterile mortar with sterile sand and water, a procedure which was open to criticism because of the possibilities of contamination from the air. More recently introduction of electrically driven mixers has made it possible to thoroughly mix samples for analysis under conditions which do not permit contamination of the sample.

Harrison⁸⁶ reported that emulsions of ripe Cheddar cheese prepared with hand emulsifiers gave plate counts nearly 10 times as high as emulsions prepared by grinding in a mortar, the method which has been quite generally used. He recommended taking several plugs of cheese which, when added to one another and prepared for analysis, would give better information on the bacterial content of the cheese.

Hucker's⁸⁷ Method for Microbiological Examination of Cheese With the Microscope. The procedure quoted here is taken from his original publication. The samples of cheese were embedded by the usual histological technic and sectioned with a Minot rotary microtome. In sectioning, the microtome was so adjusted as to give sections five microns thick. The sections were stained by the Gram method and with an aqueous solution of methylene blue.

In order to determine the effect of the embedding process upon the cheese, small measured cubes of cheese were subjected to the routine procedures. Only a slight shrinkage was found, indicating that the volume of embedded cheese when examined is approximately the same as that of the fresh sample.

MICROSCOPIC EXAMINATION

The preparations were examined with an oil immersion lens and a high power ocular, the most satisfactory combination being a 1.9 mm. fluorite objective with a numerical aperture of 1.32. Where a thick coverslip was used it was necessary to have a three mm. apochromatic objective with a numerical aperture of 1.4. Greater depth can be secured with compensating oculars than with the ordinary Huygenian oculars.

The method, although at first used only for determining the types of organisms present in the samples and as a check on the usual plate method, was found useful as

84a. Willingham. 1941. Iowa St. Coll. J. Sci. 16, 152.

87. Hucker. 1921. J. Agr. Res. 22, 93-100.

a means of determining the number of organisms present. In order to make such a computation, the microscope was so standardized as to allow an estimate of the number of organisms per gram when only a small amount of the original section was examined. This computation is quite similar to that used in the direct method of counting bacteria in milk described by Breed and Brew. This was accomplished by measuring both the diameter of the microscopic field and the thickness of the section from which the amount of cheese actually seen in each field examined was determined. Knowing the volume and specific gravity of the cheese examined, the total number of organisms per gram can readily be computed. With the diameter of the field measuring .14 mm. (140 μ), the microtome so adjusted as to cut sections of a thickness of .005 mm. (5 μ), and a specific gravity of 1, the amount of cheese examined per microscopic field would be 1/13,000,000 gm.—that is, each organism observed in a single microscopic field represents 13,000,000 per gram.

This factor may be computed by the following formula, in which any measure may be substituted:

$$\frac{1,000}{r^2 a} b = \text{factor per gram}$$

In the above formula

r = the radius of the field examined in millimeters as determined by actual measurement.

a = the thickness of the section in millimeters.

b = the specific gravity of the cheese.

The radius of the field, as has been stated, is determined by measurement with a stage micrometer and varies with the magnification and with the type of ocular used. However, it was found advisable to adjust the draw tube of the microscope so that the field would be of the greatest possible diameter without losing definition, as the greater the diameter of the field the less the increment of error in the total counts.

The thickness of the section is controlled by adjusting the microtome to cut sections of a desired and known thickness. If all the adjustments on the microtome are firm and a sharp knife is used, sections can be cut of uniform thickness with surprising accuracy. The thickness of the sections can also be measured with the fine adjustment screw on the microscope. Although not perfect, this method of measurement serves as a check upon the accuracy of the sectioning. The measurement is accomplished by focusing with the graduated fine adjustment screw on both the upper and lower surfaces of the section and noting the differences in the readings between the two levels. The difference can be read in microns where graduations are given on the fine adjustment screw.

To convert the per milliliter counts into numbers per gram, the specific gravity of the cheese must be considered. As the specific gravity of all samples has been assumed to be approximately 1, the counts are interchangeable. This assumption in regard to the specific gravity is arbitrary, but the variations in the specific gravity of Cheddar cheese are so slight that the total count is not affected to any appreciable degree. Accurate determinations did not seem practicable, as the specific gravity varies with the fat content and with the moisture and general consistency of the cheese.

With the measurements and adjustments used in this laboratory the per-gram formula resolves itself into the following:

$$r = .07 \text{ mm. (70 } \mu\text{).}$$

$$a = .005 \text{ mm. (5 } \mu\text{).}$$

$$b = 1.0.$$

$$\frac{1,000}{3.1416 \times .0049 \times .0005} \times 1 = \text{approximately 13,000,000.}$$

It is evident that this microscopic technic is subject to the limitations of any direct method of examination, many of which are unavoidable and are due to mechanical limitations or to the human error, which enters in when counts or estimates are made.

Wisconsin Curd Test for Detection of Objectionable Microorganisms in Milk for Cheese Making. This technique was proposed for detecting undesirable microorganisms in milk from which cheese was to be made. It is a simple, direct method of detecting the presence of such organisms as those which form gas. The test is made by collecting pint samples of the milk in sterile bottles. The temperature of the milk is then changed to 32.2°C.(90°F.) and 10 drops of rennin extract are added to each sample. After coagulation, the curd is cut with a sterile knife and the whey poured off. The curd is then incubated at 37°C.(98.6°F.) for about 12 hours, after which it is examined. The curd at the end of this time should be solid and have a satisfactory odor. Presence of gas-forming microorganisms will be indicated by gas bubbles in the curd. The test is especially suitable for studying the presence of undesirable organisms among the milk of various producers selling to a cheese factory.

CHAPTER 10

MICROBIOLOGY OF FROZEN DESSERTS, ICE CREAM, AND SIMILAR PRODUCTS

Frozen desserts of various types have been used by man for ages. The varieties of these products have increased greatly during recent years in the United States. Washburn¹ reviewed the history of frozen and iced products which were probably forerunners of modern ice cream. For many years little official attention seems to have been given to sanitary qualities of these products even though they are consumed in large quantities during all seasons of the year and may be made from ingredients with questionable sanitary origin. Fabian² defined "frozen desserts" as follows: They shall "include ice cream and the various kinds of ice cream, such as parfait, nut, fruit, bisque, mousse, puddings, and custards as well as sherbets, ices, milks, and special forms of desserts in which there is a combination of any two or more of the above kinds of desserts or any flavored and/or colored, sweetened water (such as popsicles), natural fruit, vegetable, or other juices with or without milk solids in which sufficient heat has been removed from the liquid mixture so as to convert it into a semisolid or solid mass with or without agitation."

The Frozen Desserts Ordinance and Code Recommended by the United States Public Health Service³ defines these products as follows:

"Frozen Desserts: A frozen dessert is any clean frozen or partially frozen combination of two or more of the following: milk or milk products, eggs or egg products, sugar, water, fruit or fruit juices, candy, nut meats, or other harmless and wholesome food products, flavors, color, or harmless stabilizer, and shall be deemed to include ice cream, frozen custard, ice milk, milk sherbet, ices, and similar products."

The ordinance then defined many of the terms used in this definition in order that control officials would know just what products were indicated. The ordinance was so worded a health officer could also control products similar to frozen desserts but which would not ordinarily be considered to come within the usual definitions of such products as ice cream, milk sherbets, and ices. The above-mentioned ordinance, which is recommended for adoption by municipalities, provides for a balanced program for control of frozen desserts. Besides the requirement for bacteriological analysis of the products, the plants in which they are made are put into three grades, A, B, and C.

As Fabian² has shown, many different ingredients may be added to frozen desserts. Many of them may carry bacteria which may negate the effects of pasteurization. The microbiology of some of these materials is discussed elsewhere in this book. As Prucha⁴ and Tracy⁵ have stated,

most of the ice cream today is made from pasteurized mix, but such ingredients as flavoring extracts, fresh fruits, berries, candies, syrups, and nut meats are added to the mix at the time of freezing and therefore do not receive the protection of pasteurization. It has been found that they may harbor a large bacterial population which may contaminate the pasteurized ice cream mix. This particular study was not for the discovery of pathogenic organisms but for the general sanitary quality of the articles. It involved a thorough investigation of their preparation as well as their use. As a result of the investigation it has been suggested that since these ingredients cannot be put into the mix prior to pasteurization, there should be sanitary laws for the preparation of such articles before use. Proper inspection and regulation should be assumed by the health authorities to assure a sanitary product.

Many of these agents are not now pasteurized. Recommendations have been made that many of them should be heated before addition to the ice cream.⁶

Origin of Microorganisms in Ice Cream. The ultimate sources of bacteria and other microorganisms in ice cream are the various raw materials from which it is made, the utensils in which they are handled, and any contamination which may reach the product during manufacture. The materials from which ice cream is made have been examined bacteriologically by different investigators. Some of the results are given below. Hall and Needs⁷ and England⁸ believed that as much as possible should be done to keep the bacterial content low. Such statements are without great significance when no attention is given to type and groups of organisms. These investigators believed that only pasteurized dairy products should be used. England stated that bacteria in ice cream came from (1) equipment, (2) plant operator, (3) ingredients added to mix after pasteurization, and (4) retail dispensing of ice cream. Usually the personal factor is the most difficult to control. While every effort has been made to keep the bacterial count low and to make ice cream mix safe by pasteurization, little attention has been paid until recently to the bacteria in materials which may be added. The Frozen Desserts Ordinance and Code of the United States Public Health Service³ prescribes as follows for various products to be used in manufacture of frozen desserts:

“The following tentative standards are recommended for ingredients not derived from milk. Egg products should have an average bacterial plate count not exceeding 200,000 per ml. or per gram. Sugar, stabilizers, fruits, nuts, chocolate, cocoa, colors, extracts, maple syrup, vanilla powder, fruit or lactic acids, candies, baked confections, or other flavoring materials should have an average bacterial plate count not exceeding 10,000 per ml. or per gram, a yeast count not exceeding 100 per ml. or per gram, and a mold count not exceeding 100 per ml. or per gram. The use of synthetic flavors and artificial colors should not be permitted unless they have been

certified as harmless by the Food and Drug Administration, U. S. Department of Agriculture."

Possible means of ridding many of the above-mentioned substances of great numbers of bacteria were reported by Brown.⁹

Cream. This may be the source of many bacteria in ice cream. It may be shipped for long distances and may be stored under conditions which permit development of bacteria. Pasteurization destroys many of these bacteria. In a study of pasteurization of ice cream mix, Hammer and Sanders¹⁰ used cream with from 81,500 to 24,700,000 bacteria per ml. with 56 per cent of the samples exceeding 1,000,000. They believed that such cream represented in a good manner the cream generally used in ice cream. Bahlman,¹¹ as did Fay and Olson,¹² found that the cream was the most important source of bacteria. Comparatively few bacteria were contributed by the other ingredients. Compulsory pasteurization of ice cream mix in several states tends to reduce the number of bacteria going into the ice cream.

Sugar. The microbiology of sugar will be discussed in a later chapter. It is probably of minor importance as a source of bacteria in ice cream. Olson and Fay¹³ and Ellenberger¹⁴ both reported quite low numbers of bacteria, i.e., around 200 per gram.

Egg Products. Microbiology of eggs is discussed in a later chapter. The Frozen Desserts Ordinance and Code Recommended by the United States Public Health Service, May, 1940,³ Edition, states that egg products should have an average bacterial plate count not exceeding 200,000 per ml. or gram.

Gelatin. Fabian and Cromley¹⁵ found that gelatin might contain many bacteria. The counts on a goodly number of samples varied from 850,000 to 4,000,000 per gram. Parfitt¹⁶ also reported some data from the bacteriological analysis of gelatin. In general, his counts were much lower than those reported by Fabian. Tracy, Ruehe, and Brannon¹⁷ reported the pH of 48 samples of gelatin varied from 4.05 to 7.35. In most cases the gelatins with a low H-ion concentration had a high bacterial count. Fay¹⁸ in a study of 34 samples of gelatin failed to find any relation between the reaction and the bacterial count. The bacterial counts ranged from less than five per gram to 20,000, and the reactions between pH 4.8 and 6.6. The keeping quality test failed to check with the relative bacterial counts. The high acidity of some of the samples had a marked deterring action on the rate of growth of the microorganisms, but in no case did the reaction completely inhibit growth when a mixed microorganism population was added. Gelatin, contaminated in the drying alleys and having a high acidity, would show very little growth. On the other hand, a nearly neutral reaction would show growth. In interpreting a low bacterial count of gelatin, one of the factors to be taken into consideration is the reaction. A low bacterial count was believed to be a fairly good index to gelatin of good sanitary quality, although the factors affecting bacterial destruction and growth, such as acidity, must be taken into consideration.

The above data do not indicate that gelatin contributes a significant number of bacteria to ice cream. Fay and Olson¹² reached this conclusion. Hammer,¹⁹ however, stated that gelatin might add large numbers of bacteria and that it was not a factor to be ignored.

The organisms predominating in raw material from which gelatin is made are aerobic sporeforming bacteria and various ordinary fungi. Henoch²⁰ found that the flora is

greatly reduced during the boiling of the bones, especially on the outer surface. The inner portion may still contain bacteria. Subsequent maceration and treatment with hydrochloric acid destroys bacteria. The entire manufacturing procedure is a fight with bacteria, especially the proteolytic species. Thexton²¹ stated that in 1935 the Canadian Federal Department of Health passed regulations stipulating that the total bacteria count of food gelatin must not exceed 10,000 per gram with the absence of coliform bacteria from .01 gram. A survey of the bacteriological quality of gelatin imported since these standards were adopted, revealed that gelatin manufacturers have been able to satisfy them in the great majority of cases.

Parfitt's Fermentation Test of Gelatin for Ice Cream Making. Weigh 10 grams of gelatin aseptically into 100 ml. of sterile distilled water containing a gram of lactose. Heat carefully at 50°C.(122°F.) to hasten solution of the gelatin. Transfer with sterile pipettes to sterile tubes and incubate at 28°C.(82.4°F.) for 18 hours and 20°C.(68°F.) for 36 hours.

Flavoring Materials. Since these are generally alcoholic solutions, they were once believed to be sterile. When fresh fruits are used for flavors many microorganisms of diverse types may be introduced. Fabian²² suggested a standard of not over 5,000 bacteria per gram for flavoring sirups and fruits. According to results published by Prucha²³ such a standard would cause complications at present. Tracy and Brown²⁴ found that flavoring materials could be heated before use. Experiments with flavoring extracts pasteurized at 62.8°C.(145°F.) for 30 minutes indicate that if doubt exists as to the sanitary quality of the extract, heating can be resorted to without decreasing the value of the flavor of ice cream. The trials indicate that vanilla extract subjected to this treatment can be used satisfactorily.

Information on this problem is not limited to recent investigations. Hammer,²⁵ as early as 1912, reported the presence of bacteria in vanilla extract. He analyzed five samples of vanilla extract and found only 2,300 bacteria per ml. in the most heavily contaminated sample.

Coloring Materials. Little bacteriological work seems to have been done on colors used in frozen desserts. Smallfield²⁶ and Prucha²³ found these materials to carry many bacteria. The dry, powdered colors, according to Smallfield's results, contained but a few thousand microorganisms while the liquid colors contained as many as 198,000,000 bacteria per ml. in some of them. Prucha found some to be heavily seeded, and in some others coliform bacteria were present. Survival of *Eberthella typhosa* and *Staphylococcus aureus* in three different coloring materials for two weeks was observed by Brown.⁹ Results of a more comprehensive investigation by Boyles²⁷ has, in general, confirmed the conclusions just presented. He examined 98 samples of dyes, the total microbial content varying from 10 per ml. to 26 million. Twenty-six of the 98 samples examined contained over 400,000 per ml. and 17 harbored coliform bacteria. Molds, clostridia, and thermophilic bacteria were absent. Presence of large numbers of bacteria and coliform bacteria indicated that some of the dye solutions had been prepared under insanitary conditions. The older solutions frequently had greatest number of microorganisms.

Nut Meats and Fruits. The great amount of bacteriological work which has been done on nut meats indicates that they might seed the ice cream mix with many bacteria, some of which have been found by Prucha⁴ to be members of the coliform group. These products are discussed in a later chapter in this book. Tracy²⁸ mentioned the fact that while the mix is pasteurized and utensils are carefully cleaned, the results of these new standard procedures are largely nullified by addition of many materials which may be

of questionable sanitary quality. Brown⁹ greatly improved the sanitary quality of nut meats for frozen desserts by immersing them in boiling sugar solution after which they were dried in an oven. In view of the conditions which Tracy revealed, he believed that some treatment was necessary to rid nut meats of the microorganisms. Fifty per cent of specimens he collected from ice cream plants carried *Escherichia coli*. He tried several methods. Hot sucrose solutions (25-75 per cent) at 82°C. (180°F.) or boiling, and hot butter at 97.4°C. (208°F.) or boiling were the best. Efficacy of these procedures was shown by using inoculated nut meats.

Condensed Milk. The microbiology of this product is discussed in Chapter 11.

Fruit Products. Both fresh and frozen fruits may be used. Fresh fruits may yield a better flavor, but many believe today that frozen fruits may be just as satisfactory. Fellers and Mack,²⁹ Joslyn and Cole,³⁰ and Sarber³¹ have supported their use. As shown elsewhere in this book, frozen fruits are not sterile and may carry many bacteria, yeasts, and molds. Should they be added to ice cream mix, the count may be materially raised.

Homemade Ice Cream. More adequate methods of refrigeration in the home have stimulated greater use of homemade ice cream and similar products. Little was known about the bacteriological quality of such products until Foltz and Martin³² published results of examination of many samples collected in Manhattan, Kansas. The bacteriological quality of homemade ice cream averaged lower than commercial ice cream examined. Foltz and Martin believed that this was due to use of unpasteurized products in some cases. When pasteurized milk and cream were used, an average bacterial count of 17,000 per ml. was secured which compared favorably with the counts of commercial samples. Presence of coliform bacteria in a few samples which showed high counts was assumed to indicate bad contamination of the product.

Machinery and Utensils. The machinery may increase the bacterial count in two ways: it may contribute bacteria to the mix, and may break up the clumps. Fabian³³ studied this question very thoroughly and suggested means for cleaning and sterilizing machinery. These procedures need not be reviewed here, but should be read by those who control and operate ice cream plants. It is quite important that pasteurized mix should not be contaminated by dirty utensils. The lines and apparatus must be thoroughly steamed to prevent seeding the mix and thus negating the effects of pasteurization. Similar advice was given by Fay and Olson.¹²

In order to make certain that the freezer was unimportant in the contamination of ice cream, Ellenberger¹⁴ ran 500 ml. of sterile water through it. Plate counts on this water varied from 10 to 55 colonies per ml, with an average of 28. Thus it was shown that the freezer would not contribute significant numbers of bacteria. Hammer,³⁴ however, agitated sterile water in a freezer and in five tests secured counts of 3700, 300, 1195, 8050, and 141,500 per ml.; indicating that the freezer under some conditions may be important. Fay and Olson¹² reported that thorough washing and cleaning of all equipment with live steam were essential factors in the production

of ice cream with a low count. Utensils seem to have the same relation to the bacteria content of ice cream that they do to milk.

Prucha³⁵ believed that utensils should be exposed to a temperature of at least 76.7°C.(170°F.) for at least 15 minutes or 93.3°C.(200°F.) for five minutes in a steam cabinet or a jet of steam for one minute. Chlorine solution with at least 50 p.p.m. of chlorine applied one minute would also be satisfactory. If hot water is used, the utensils should be immersed for two minutes.

Another utensil which has been much studied from the bacteriological viewpoint is the container in which ice cream is distributed. Paper ice cream containers have replaced metal containers in many cases for their advantages are obvious. They parallel those which obtain for the single-service paper milk container. Bacterial counts by Speck and Black³⁶ of open-top ice cream containers obtained from retail stores varied widely and apparently correlated with storage conditions, air and dust contamination being most important. Cylindrical containers closed during manufacture with tight crown tops had consistently low counts. Paper ice cream dishes in nests and inverted at the ice cream bar until used gave low or negative counts. Containers at one ice cream plant sampled directly from the original package from the paper manufacture gave high counts, a condition not found in a different brand sampled at another plant. Some typical organisms isolated were species of micrococci (11 strains), *Alkaligenes* (3), *Sarcina* (2), *Bacillus* (1), and *Achromobacter* (1). The presence of some of these organisms in containers directly from a manufacturer suggested contamination during manufacture by polluted water. Inoculations, using five per cent of the liquid in which the swabs were disentangled, into brilliant green lactose peptone bile, failed to reveal the presence of coliform bacteria.

Speck and Black³⁶ found the swab method more practical for the examination of open-top paper containers than rinse methods. They swabbed the surface with one moist and one dry swab. After use, the swab was thoroughly broken and disentangled in a 40 ml. dilution blank. This technique would be especially suitable for open-top containers but might have decided limitations with containers that are practically closed.

Speck and Black's³⁶ Method for Bacteriological Examination of Paper Ice Cream Containers. This procedure consisted of swabbing the interior of the container with sterile swabs. The swabs were made by winding cotton onto the end of a six and one-half inch wooden applicator to a thickness of one-fourth inch and a width of one inch. The swabs were wrapped in pairs in brown paper and sterilized at 120°C.(248°F.) for 30 minutes in the autoclave. Standard nutrient agar adjusted to a pH of 7 was used for plating. Plates were poured in duplicate and incubated at 37°C.(98.6°F.) for 48 hours. Two swabs held in the same hand, the first moistened from the 40-ml. water blank and the second dry, were used to swab the inside of the container thoroughly. Both swabs were then broken into the 40-ml. dilution blank and shaken until disentangled. One-ml. portions were then plated. The average counts were reported as bacteria per container.

Ice Cream Scoops. Ice cream is usually dispensed by means of scoops. These have been found to be a source of bacteria in ice cream in retail stores. Krog and Dougherty³⁷ examined over 200 samples taken from the surface of ice cream sold in bulk. High counts were secured when the vendor's scoop was used and only moderate counts when the sample was collected with a sterile spoon. With subsurface samples (at least one inch below) equally high figures were obtained using the vendor's scoop and very low figures with a sterile spoon. The scoops are usually kept in a vessel containing cold water and samples of such water showed exceedingly high counts. That the scoop and the way it was kept is largely responsible for the high counts was shown by further figures with the scoops kept on dry racks and rinsed in either hot or cold running water before and after each usage. Studying the same subject Geiger³⁸ found that 124 scoops had bacterial counts under 10,000 per ml., 226 had over 100,000, and 97 had over 1,000,000 per ml. Abele³⁹ examined the water in which the scoops were placed. A study of 40 samples of such water revealed that the bacterial content of the water ranged from 600 per ml. to 20,000,000 per ml. The average count from five receptacles into which a small stream of water was constantly flowing was 9,500 per ml., the extremes being 600 and 77,000 per ml. Hopkins⁴⁰ and Fabian and Hook⁴¹ found, at fountains where the dippers were kept in running water, the total bacterial count as well as the coliform count of the water to be less than where still water was used. Eighty-one per cent of the samples of still water had a plate count in excess of 100,000 bacteria per ml. while only 18 per cent of the samples of running water exceeded 100,000 bacteria per ml. Ten of the 18 per cent of samples of running water which exceeded 100,000 ml. were probably high because the water was running too slowly through the receptacle containing the dippers.

A general relationship between the total bacterial count and the coliform bacteria content of retail ice cream exists when the count exceeds 100,000 bacteria per ml. Below this, the relationship is less marked. However, there seems to be no direct correlation between the *Escherichia-Aerobacter* content of the ice cream being served and the dipper water. Further information on this question was published by Horn.⁴² Most of the results just quoted are counts only. Little attention was given to types of bacteria. Do these counts always indicate what they are supposed to?

The Ice Cream Mix. When the various ingredients to be used in a frozen dessert have been combined and are ready to be frozen, the mixture is spoken of as the "mix." The Frozen Desserts Ordinance and Code recommended by the United States Public Health Service, May, 1940, Edition,³ defines the term as follows:

C. *Mix*. Mix is the unfrozen combination of all ingredients of a frozen dessert with or without fruits, fruit juices, candy, nut meats, flavor, or harmless color.

It frequently happens that there are fewer bacteria per ml. in the mix than in cream. This is probably due to dilution of the cream with other constituents which are considerably freer from bacteria. It is possible that the sugar added to the mix may kill some of the bacteria. Since the ice cream mix contains milk products and since many of them are liable to contain living *Mycobacterium tuberculosis*, manufacturers and public health officials have found it desirable to pasteurize it. The Public Health Council of the State of New York, for instance, passed a law, effective April 1, 1929, to the effect that ice cream mix should be pasteurized at 65.5°C. (150°F.). Other states have similar laws although there is a little variation in the temperature and time.

Pasteurization of Ice Cream Mix. This is necessary in order that ice cream may be a safe food. Ice cream mix is a different product from fluid milk and presents more problems; consequently times and temperatures are higher for ice cream mix than for milk.

Fabian's⁴³ summary of epidemics caused by ice cream suggested that pasteurization of the mix should be thoroughly studied. While the temperatures now used in milk pasteurization are well supported by adequate experimental data, such is not the case for ice cream mix. Recommended times and temperatures vary widely. Those who are familiar with the problems involved appreciate why this is the case. Some bacteriological work has been done on the problem but whether it is reliable from the bacteriological viewpoint is open to question.⁴⁴

Fabian and Cromley¹⁵ and Hammer and Sanders¹⁰ both reported significant decrease in bacterial content by pasteurization at 65.6°C. (150°F.) for 30 minutes. Fay and Olson¹² stated that the bacterial content of the mix, after pasteurization, depended on the number originally present. Pasteurization at 62.8°C. (145°F.) for 30 minutes, followed by homogenization, resulted in counts of less than 100,000 bacteria per gram in the finished product, even with raw mixes containing as high as 34,000,000 bacteria per gram.

The subject has also been studied by the committee on dairy products and eggs of the American Public Health Association (Schrader⁴⁵). A survey of methods used by 500 ice cream companies revealed the use of temperatures and holding periods ranging from 60°C. (140°F.) for 30 minutes, up to 85°C. (185°F.) for 10 minutes. Experiments on a commercial ice cream mix, inoculated with pathogenic bacteria, showed that 62°C. (143.5°F.) for 30 minutes allowed an ample margin of safety. A further report confirming this work by Oldenbusch, Frobisher, and Schrader⁴⁶ is mentioned later. Brannon⁴⁷ believed that 65.5°C. (150°F.) to 71.1°C. (160°F.) would destroy all pathogenic bacteria in ice cream mix.

Significance of the presence of coliform bacteria in many food products, especially milk and dairy products, is still a controversial subject.

As is the case with fluid milk, a few bacteriologists believe that the organisms in ice cream mix mean faulty processing including pasteurization. Accordingly it was necessary to know something about the resistance to heat of coliform bacteria in ice cream mix. Fabian and Coulter⁴⁸ reported that the thermal death point of 33 cultures of *Escherichia coli*, seven of *Aerobacter aerogenes*, and four of unidentified lactose-fermenting organisms isolated from water showed variation when heated in ice cream mix at 60°C.(140°F.), 62.8°C.(145°F.), and 65.5°C.(150°F.) for 30 minutes. Four determinations were made at 60°C.(140°F.), the number surviving expressed in per cent being 51.2, 39, 36, and 57, respectively. When the temperature was increased to 62.8°C.(145°F.) the number surviving decreased to 22.7, 6.8, 2.2, and 22.7 per cent, respectively. At 65.5°C.(150°F.) the number surviving still further decreased to 0.0, 2.4, 2.4, and 9.1 per cent, respectively, while at 68.3°C.(155°F.) no cultures tested survived. A larger number of cultures, when heated to corresponding temperatures, survived in ice cream and skim milk. Different ingredients used in making ice cream failed to show any protective action. These data indicate that the critical temperature for the *Escherichia-aerogenes* group in ice cream is about 65.5°C.(150°F.). Previous work by Fabian⁴⁹ with coliform bacteria had shown that 68.3°C.(155°F.) was necessary to kill all of the cultures. Dubois and Martin⁵⁰ reported that exposures to 62.8°C.(145°F.) for 20, 25, and 30 minutes; to 65.6°C.(150°F.) for 20, 25, and 30 minutes; to 71.1°C.(160°F.) for 10, 15, and 20 minutes; to 76.7°C.(170°F.) for 2, 5, and 10 minutes; and to 82.2°C.(180°F.) flash, yielded results differing insufficiently to be measured by plate counts. In mixes made from previously pasteurized dairy products the flora after pasteurization was about evenly divided between peptonizing and alkali-forming and inert groups of bacteria; in mixes made from previously pasteurized dairy products the flora after pasteurization consisted largely of slow acid-forming bacteria. In only one case did rapid acid-forming bacteria survive the exposures. The predominating types of organisms surviving pasteurization (slow acid formers) were small Gram-negative rods which grew well at 26.7°C.(80°F.) but not at 37°C.(98.5°F.). Presence of coliform bacteria along with a negative phosphatase reaction, according to Nelson,⁵¹ indicates contamination after pasteurization. Several strains were found to survive pasteurization at 62.8°C.(145°F.) for 30 minutes, and phosphatase tests were positive. At 65.6°C.(150°F.) they were destroyed in 10 minutes, but 30 minutes were necessary for destruction of phosphatase.

One of the important factors involved in pasteurization of ice cream mix is the effect which ingredients of the mix may have on survival of microorganisms. Sugar in higher concentrations is known to cause them to survive longer. Beavens,⁵² Fay,⁵³ and Fabian and Coulter⁴⁸ have

shown this. Results of investigations by others have been mentioned in other chapters.

Various opinions have been expressed as to what pasteurization of ice cream mix is. Armstrong⁵⁴ believed that 67.2°C.(153°F.) was required. He mentioned the recommendations of the International Association of Milk Sanitarians that 68.3°C.(155°F.) for 30 minutes should be used or 82.2°C.(180°F.) for 16 seconds, or higher in each case.

The Frozen Desserts Ordinance³ proposed by the United States Public Health Service includes the following definition of pasteurization:

Pasteurization: The term "pasteurization," "pasteurized," and similar terms shall be taken to refer to the process of heating every particle of mix to at least 68.3°C.(155°F.) and holding at such temperature for at least 30 minutes in approved and properly operated equipment, providing that nothing contained in this definition shall be construed as debarring any other process which has been demonstrated to be equally efficient and is approved by the state health authorities.

Effect of Pasteurization on Pathogenic Bacteria in Cream. Although much work has been done on the thermal death time of nonpathogenic bacteria in milk, much less has been done to determine the longevity of pathogenic bacteria at pasteurization temperatures. In order to secure information on this question Oldenbusch, Frobisher, and Shrader⁴⁶ suspended two strains of *Eberthella typhosa*, two of beta type hemolytic streptococci (one from scarlet fever and one from septic sore throat), and one culture of *Mycobacterium tuberculosis* of the bovine type in cream with 50 per cent butterfat content. This had been previously sterilized in an autoclave for 30 minutes at 15 pounds' pressure. The determinations were carried out by placing 9.9 ml. of cream into each of a series of small bottles. Just before the experiment, the bottles of cream were heated to the five temperatures which were used between 57.2°C.(135°F.) and 62.8°C.(145°F.). Samples were taken at various intervals and subjected to bacterial examination which would reveal viability of the organism under study. The streptococci did not survive heating in cream at 57.2°C.(135°F.) for five minutes nor at 60°C.(140°F.) to 61.2°C.(142°F.). *Eberthella typhosa* heated at 57.2°C.(135°F.) were killed in less than 10 minutes, at 60°C.(140°F.) in less than five minutes, and at 61.2°C.(142°F.) to 62.8°C.(145°F.) in less than three minutes. Tubercle bacilli in cream were killed in less than 20 minutes when heated to 57.2°C.(135°F.), in less than 10 minutes at 60°C.(140°F.), in less than seven minutes at 61.2°C.(142°F.) to 62°C.(143.5°F.), and in less than three minutes at 62.8°C.(145°F.). Failure to produce infection in guinea pigs was interpreted as meaning that the organisms had been killed. The authors, therefore, concluded that 30 minutes heating in cream at 62°C.(143.5°F.), recommended by a committee of the American Public Health Association for the pasteurization of milk, allows an ample margin of safety for the pasteurization of cream and commercial ice cream mix.

Effect of Homogenization on the Number of Bacteria in Ice Cream. Ice cream mixes are generally homogenized to yield a more thoroughly mixed

54. Armstrong. 1940. *Ice Cream Rev.*, April 1940, 41-42.

product. The mix is forced through a very small opening under high pressure. The procedure apparently affects the bacterial count. Fabian⁵⁵ stated that homogenization tends to reduce the size of the clumps. The bacterial contamination in the homogenizer was said to be of the same type as is normally found in milk. The clumps of bacteria were broken up and the count was increased. Fay and Olson¹² observed an increase in the count 18 times and a decrease 10 times from homogenizing the mix. Similar results were also reported by Hammer and Sanders¹⁰ who cautioned that the homogenizer must be carefully cleaned else it would seed the mix with more bacteria.

The Phosphatase Test Applied to Ice Cream. This test which has enjoyed such a wide application to milk has also been used to control pasteurization of ice cream mix. Nelson⁵⁶ said the phosphate test could be effectively used for detecting the efficiency of pasteurization of ice cream mixes. Careless handling after pasteurization was believed to be indicated by presence of coliform bacteria. Hahn and Tracy⁵⁷ found Scharer's modification of the phosphatase test to be possible for detection of variations in the time and temperature of pasteurization of ice cream mixes provided they were not colored or flavored. Use of all raw or partially pasteurized milk products in building a mix had no effect on the final phenol value if the mix was pasteurized at 65.6°C.(150°F.) or above. However, at 63.8°C.(147°F.) or below, the mix made from raw milk products gave a considerably higher final phenol value than did the mix made from partially pasteurized milk products. Subjecting raw milk and ice cream mix made from all raw milk products to the same heat treatment by heating to 65.6°C.(150°F.) or above and holding for 30 minutes resulted in the same final phenol value for both milk and mix. Temperatures below 65.6°C.(150°F.) resulted in a higher final phenol value for the ice cream mix than for the milk. The condensing process decreased the amount of phosphate enzyme present. Increasing the serum-solid content of the mix had no effect on the final phenol value when the mix was pasteurized at 65.6°C.(150°F.) for 30 minutes. Storage of pasteurized, unflavored, and uncolored ice cream at -28.8°C.(-20°F.) over a period of two weeks did not alter appreciably the phenol value. Storage of such ice cream for 12 weeks resulted in marked decreases in the phenol value of all samples except those made from mix samples taken 20, 25, and 30 minutes after reaching 65.5°C.(150°F.). Samples heated to a lesser degree than 20 minutes at 65.5°C.(150°F.) showed a sufficient phenol value for the sample to be considered under-pasteurized. Pure vanilla had no effect on the phenol value, while artificial and imitation vanilla compounds caused a slight increase and coumarin and vanillin caused appreciable increase in the phenol value. The addition of coloring material to ice cream mix in many instances affected the phenol value unless the coloring matter was precipitated with the protein upon the addition of lead acetate. Test runs

55. Fabian. 1925. *J. Dairy Sci.* 8, 246-269.

on commercial samples of ice cream mix gave indication of complete pasteurization in all but one case.

Scharer⁵⁸ believed that the pasteurized mix should show no phosphatase activity. This would probably mean adequate pasteurization for destruction of pathogenic bacteria because observations by Caulfield and Martin⁵⁹ indicated that sugar protected the enzyme against incubation at temperatures of 61.1°C.(142°F.) to 62.7°C.(145°F.) in 30 minutes. At temperatures around 65.5°C.(150°F.) the enzyme was destroyed regardless of presence or absence of sugar.

Bacterial Content of Ice Cream. Results of many investigations are available in the literature. In general, bacterial counts have been used to judge the conditions under which the ice cream was made and handled. The count alone was probably of much greater significance in former times than it is now. Other methods have been proposed to either supplement the count or replace it. Wiley⁶⁰ and his colleagues reported many bacteria in ice cream manufactured in the District of Columbia. Fabian⁶¹ believed that the count could be kept below 100,000 per gram. However, Ayers and Johnson⁶² never found summer samples to be below this limit. Only 14.28 per cent of the winter samples were below this limit. Palmer⁶³ reported bacterial contents between 20,000 and 8,000,000,000 per ml. The cream and utensils contributed most of the bacteria. Ice cream samples collected in London by Rawlinson⁶⁴ showed gross contamination. Olson and Fay¹³ and Fabian⁶⁵ agreed that bacterial numbers could be kept down by careful methods of manufacture. The former accepted Fabian's proposed standard of not over 100,000 bacteria per gram. Hammer¹⁹ reported an average of 19,920,000 bacteria per ml. in ice cream collected on the Des Moines market. He also believed that low-count ice cream could be produced if proper care was used.

Bacteriological examination of 63 samples of ice cream by Chalke⁶⁶ gave counts varying from 3,000 or less to over one million per ml., while *Escherichia coli* was present in seven cases in .001 ml., in 21 in .01 ml., in four in .1 ml., and one case only in 1.0 ml. An analysis of the findings shows that the small vendor is worst offender, the most "cold mix" samples are heavily contaminated while "pasteurized-mix" nearly always yielded low bacterial figures, that visiting and education work can be very effective and result in a marked lowering of the bacterial content, and that many possible sources of contamination have to be considered.

Effect of Aging on Bacteria in Ice Cream Mix. Fay and Olson observed little change in the bacterial content of ice cream mix when stored below 7.2°C.(45°F.) for 16 to 24 hours. Hammer and Goss⁶⁷ also reported no

increase in numbers of bacteria of mix aged for days at 0°C.(32°F.). Similar results were secured by Peterson and Tracy⁶⁸ but Fabian and Cromley¹⁵ reported that aging at 2°C.(35.6°F.) did increase the plate count. These increases were not regular nor were they significant. Mueller and France⁶⁹ attempted to ascertain whether or not the aging temperature of 20°C.(68°F.), considered desirable when gelatin is used in the manufacture of ice cream, had an unfavorable effect on the bacterial count of the finished product.

It was found that aging a pasteurized mix for six hours at 68°F. whether followed by aging for 18 hours at 3.3°C.(38°F.) or not, had no significant effect on the increase in the number of bacteria. On the other hand, aging an unpasteurized mix under similar conditions resulted in a material increase in the number of bacteria present. There was no definite increase in bacterial count until after the tenth hour in ice cream mixes aged for 24 hours at 68°F. Aging a mix for 24 hours at 38°F. did not cause a material increase in the number of bacteria.

Effect of Freezing on the Number of Bacteria in Ice Cream. From the nature of the freezing process, one would expect an increase in the number of colonies on plates made from ice cream over the number on plates made with the mix before freezing. Ellenberger¹⁴ found this to be true in almost every case. He observed an average increase of 48 per cent. Gordon, Prescott, Heinemann, and Pease⁷⁰ reported similar observations. The increase in the number of bacteria may be explained in the same manner that it is explained by passing milk through a clarifier—to the breaking up of clumps of bacteria during the beating of the mix. Similar increases in the colony count of ice cream owing to freezing have been observed by Fay and Olson¹² and Fabian and Cromley.¹⁵

Effect of Hardening and Storage on the Number of Bacteria in Ice Cream. When ice cream comes from the freezer it is soft and plastic and must be hardened before storage. It is run into five- or 10-gallon containers or worked into novelties and placed in the hardening room at low temperatures. Hardening alone would probably not destroy many bacteria. Hammer and Goss⁷¹ and Fay and Olson,⁷² however, reported decreases in numbers of viable organisms which amounted to as much as 75 per cent in some cases. In a few cases the former investigators observed increases in bacterial counts after hardening. These were believed to be due to manipulation of the sample rather than actual development of bacteria. Fay and Olson's results agreed quite well with those of Hammer and Goss in that hardening and storage for a few days resulted in a decrease of living bacteria.

Most ice cream is stored for varying lengths of time and several investigators have studied the effect of storage on the bacterial content. Esten

and Mason ⁷³ reported no marked change in the bacterial content of ice cream kept frozen for at least a month. By the use of litmus lactose gelatin plates, they noticed little change in the percentage of acid-forming and liquefying bacteria. Other investigators, however, have reported decreases in the number of bacteria. Stiles and Pennington ⁷⁴ stored ice cream for 34 days. They observed in some cases small increases in the number of bacteria during the first three days, after which there was a decrease to the 14th day; a marked increase occurred on the 27th day, followed by a sharp decline to below the original count on the 34th day. Now and then an investigator has reported increases in bacterial numbers during storage. Ellenberger ¹⁴ was one of these. Hammer ³⁴ and Hammer and Goss ⁶⁷ could not observe a tendency for the number of bacteria in ice cream to increase. There was rather a general tendency for the number of bacteria to decrease. Fabian and Cromley ¹⁵ made the same observation.

Effect of Season on Number and Types of Bacteria in Ice Cream. Ayers and Johnson ⁶² found that the average number of bacteria in ice cream is lower during the winter months. A summary of their results is given in the following table:

Item	Summer series (94 samples)	Winter series (91 samples)
Average number of bacteria per ml.	37,859,807	10,388,222
Maximum number.....	510,000,000	114,000,000
Minimum number.....	120,000	13,000

These authors, as did Ellenberger ¹⁴ also, determined the percentage of groups of bacteria in ice cream by the Ayers' milk tube method. Their data are tabulated below:

	Ayers' samples		Ellenberger's experimental samples
	Summer	Winter	
	<i>Pct.</i>	<i>Pct.</i>	<i>Pct.</i>
Acid coagulating.....	49.82	30.84	46
Acid forming.....	20.72	38.03	29.4
Inert bacteria.....	13.98	4.81	22.7
Alkali formers.....	1.86	5.42	0.6
Peptonizers.....	13.62	20.90	1.3

Ellenberger also studied the influence of pasteurization of the cream on the percentage distribution of the above groups. The most noticeable difference was that in all except one sample the pasteurized cream group showed but few inert bacteria as compared with the raw cream group. There was at the same time an increase in the total acid group.

Distribution of Bacteria in Ice Cream. Since statements were made that bacteria were very unevenly distributed in ice cream, Ayers and Johnson ⁷⁵

73. Esten and Mason. 1915. Conn. Agr. Expt. Sta. Bull. 83, 128-134.

74. Stiles and Pennington. 1907. U. S. Pub. Health Serv., Hyg. Lab. Bull. 41.

75. Ayers and Johnson. 1917. U. S. Dept. Agr. Bull. 563.

collected samples from different places in cans of ice cream. Contrary to the general opinion, they found that the bacteria were quite evenly distributed and that analysis of one sample yielded results which represented the condition of different portions of the same gallon. Furthermore, storage for 11 days in a commercial ice cream cabinet did not cause uneven distribution of the bacteria. A goodly number of samples taken from commercial freezers yielded counts which checked within the usual limits of error of bacteriological analyses. These investigators observed no greater variation in counts when the plates were incubated at 37°C.(98.6°F.) for 48 hours than when incubated at 30°C.(86°F.) for five days.

Homemade Ice Cream. For various reasons, homemade ice cream may contain more bacteria than commercial ice cream. This is due to factors not given as much attention by the homemaker as by the commercial ice cream maker. One hundred samples from 40 homes were examined by Foltz and Martin.⁷⁶ The logarithmic average standard plate count of all samples was 171,000 per ml. and the logarithmic average coliform count was 70 per ml. Both standard plate count and coliform count were much higher on those samples frozen with salt and cracked ice in tub freezers than were the samples frozen in the freezing units or pans of mechanical refrigerators. Samples frozen from pasteurized dairy products were much lower in both counts than those from unpasteurized dairy products. The bacteriological quality of homemade ice cream averaged lower than that of samples of commercial ice cream collected in a survey made somewhat earlier, more of the homemade samples being found in the high-count groups. This was undoubtedly due largely to the use of unpasteurized milk products in the making of the mix.

Bacteriology of Sherbets and Ices. These have usually shown a much lower bacterial content than ice cream and frozen desserts. Results of only a few investigations have been reported even though these products have enjoyed considerable popularity. Fay⁷⁷ examined 21 samples of orange sherbet and found less than 200 bacteria per gram in 10 per cent of the samples, between 200 and 100,000 per gram in 80 per cent of the samples, and more than 100,000 per gram in 10 per cent. Hammer and Goss⁷¹ had previously examined 17 water sherbets which showed bacterial counts between six and 7,800 per ml. Quite different results were secured by Gundel⁷⁸ on sherbets made in Germany. He believed that ices and ice cream might become contaminated during manufacture by various agents. Total counts of from 8,000 to 14,500,000 per ml. were secured on samples obtained from trade sources (street vendors, hotels, and restaurants). More than half of the samples contained more than one million bacteria per ml. *Escherichia coli* content was variable but many samples were positive for the organism in .001-ml. quantities or less. Gundel believed that more attention should be given to these products.

BACTERIAL EXAMINATION OF FROZEN DESSERTS

Many investigators have suggested methods for this purpose. Most of them have involved use of the bacterial plate count as an index of quality and general conditions under which ice cream has been made. As time has progressed and new methods have been developed for other dairy products, especially fluid milk, they have been applied to ice cream. Three methods for determining quality of ice cream were used by Weinzirl and Harris⁷⁹: (a) total count of bacteria (48 hours at 37°C.[98.6°F.]); (b) tests for members of the coliform group, and (c) the anaerobic spore test. They believed that the total count revealed the results of contamination and subsequent multiplication of bacteria introduced but that it did not distinguish between the two. The test for members of the coliform group functions much like the total count but was somewhat more specific in indicating unsanitary conditions. The anaerobic spore test was believed to show unsanitary conditions only. It fails to distinguish between the spores added in the sugar and those resulting from unsanitary conditions.

Control of any food product ought to involve use of every method which will give helpful information. Results of only a few investigations in which various methods were compared have been published. Martin, Nelson, and Caulfield⁸⁰ examined 318 samples collected from over 300 ice cream manufacturers in Kansas for the standard plate count; the minimum amount of samples containing coliform organisms; the phosphatase test; the butter-fat test; the weight per gallon; and the flavor, body, and texture, and color and package scores. Standard plate counts of 100,000 or less per ml. were obtained on 59.8 per cent of all samples. A slightly higher percentage of samples from counter freezers than from wholesale manufacturers were in the lower count range. Only 17 of the 313 samples gave a positive phosphatase test. However, these authors stated that 126 other samples would have been considered under-pasteurized, if suitable controls had been run. These would have been under-pasteurized or contaminated with unpasteurized dairy products. Failure of results of various methods of examination to agree, prompted Martin, Nelson, and Caulfield⁸⁰ to conclude that it was difficult to determine the true quality of a sample by a few tests.

Somewhat the same approach to the problem was made by Yale and Hickey⁸¹ who examined samples collected in a small city in central New York State. Both total and coliform counts were determined for 77 process samples from seven local plants, 137 ice cream samples from 12 retail stores, and 36 dipper-water samples from 18 establishments. Enumeration of coliform bacteria was more sensitive than either standard nutrient agar or tryptone agar counts in revealing contamination by ice cream dippers and dipper waters. Three of the manufacturers had all standard agar plate counts of store samples under 100,000 per gram. Yale and Hickey believed the greatest need for improvement in sanitation to be in dispensing bulk ice cream.

Influence of Temperatures of Incubation on Bacterial Counts. The nature of ice cream suggested to some of the investigators that more information should be available on the effect of temperatures of incubation on the colony counts. The average count of plates incubated at 30°C. (86°F.) for five days was almost two and one-half times the count on plates incubated for two days at 37°C. (98.6°F.). In no case did plates incubated at 37°C. show as many colonies as those incubated at 30°C. The counts on plates incubated at 20°C. (68°F.) averaged three times as great as those on plates at 37°C. The results of this comparative study seemed to indicate that the incubation of plates for seven days at 20°C. tended to show the true number of bacteria in ice cream. Ayers and Johnson⁷⁵ compared the incubation of plates at 37°C. for two days and at 30°C. for five days. They observed that the incubation of plates at 37°C. for 48 hours did not give counts which showed any greater variation than those obtained by incubation at 30°C. for five days. The count obtained from plates incubated for five days at 30°C. was practically double that from plates incubated at 37°C. for 48 hours. These investigators observed less variation when dilutions were used which gave about 200 colonies on the plates.

The Committee on Bacteriological Methods of Analyzing Dairy Products of the American Dairy Science Association, which prepared a report on methods of ice cream analysis, made indefinite statements about incubation of the plates. They stated that a "more complete" count would be obtained by incubating the plates for 48 hours at 37°C. followed by one week at room temperature. Plate counts probably do not indicate the actual number of bacteria in ice cream or ice cream mix. Fabricius and Hammer⁸² reported that when standard agar was used as the plating medium, serious discrepancies were found in the counts secured by plating different dilutions, especially the 1 to 1,000 and 1 to 10,000 dilutions. When one per cent of sucrose was added to the medium, these discrepancies did not occur. The presence of sucrose also frequently made the colonies so much larger that they were more easily counted. Various types of organisms were found to be responsible for pin-point colonies on plates poured with ice cream dilutions.

Satisfactory sampling is one obstacle in bacteriological examination of ice cream. Data in the past have, in general, been based on the gravimetric and volumetric basis. Fay⁸³ compared the data secured by both methods. The errors which might be introduced by gravimetric methods are more apparent than real. Fay concluded that just as reliable data could be secured with the volumetric as with the more tedious gravimetric sample. He also believed that a 10-ml. would be preferable to one-ml. sample.

Influence of Plating Medium on Bacterial Content of Ice Cream. Substitution, in the seventh edition of *Standard Methods for the Examination of Dairy Products 1940*, of dextrose-tryptone-glucose skim milk agar for the nutrient agar which had been used for many years prompted investi-

82. Fabricius and Hammer. 1931. Iowa Agr. Expt. Sta. Bull. 285.

83. Fay. 1930. J. Dairy Sci. 13, 40-47.

gations in which the two media were compared. As far as ice cream is concerned, the change was made without information as to how the new medium would work with ice cream. Abele⁸⁴ presented a few data which prompted him to conclude that standards for ice cream would not have to be changed, even though the new medium would reveal many more bacteria. This would seem to indicate that plate count standards do not mean much.

Many comparative studies were made in which the old plating medium was compared with the new one mentioned above.

Robertson⁸⁵ reported results of comparisons made in five different ice cream plants of bacteria counts obtained by use of standard nutrient agar then in use and with tryptone-glucose agar at both 32°C. (89.6°F.) and 37°C. (98.6°F.). The latter was found to give definitely higher bacteria counts than standard nutrient agar. The higher count with tryptone-glucose agar is thought to be a more accurate criterion of the actual number of organisms present in ice cream than is the count secured with standard nutrient agar. As to the incubation temperature, duplicate counts from the same dilution waters have been shown to be from 30 to 50 per cent less variable at 32°C. than at 37°C. Similar results were reported by Foltz and Martin⁸⁶ who made bacterial counts on 279 samples of commercial ice cream using standard nutrient agar and 37°C. incubation temperature, and tryptone-glucose-skim milk agar incubating the plates at 37°C. and 32°C. The logarithmic average of the standard agar counts at 37°C. was 96,500, and the counts obtained on tryptone agar at 37°C. and 32°C. incubation temperatures were 137 and 192 per cent, respectively, of the standard agar count. The arithmetic average of the standard agar count was 5,490,000, and the counts obtained on tryptone agar at 37°C. and 32°C. were 132 and 156 per cent, respectively, of the standard agar count. The mean and median ratios of tryptone agar count at 32°C. to the standard agar count at 37°C. were 4.11 and 1.52, respectively. The mean ratio of the tryptone agar count at 37°C. to the standard agar count at 37°C. was 2.46 and the median ratio was 1.25.

White⁸⁷ covered about the same ground by making comparative total bacterial counts of 82 samples of ice cream on standard nutrient agar, standard nutrient agar plus one per cent sucrose, and two types of tryptone-glucose-milk agar, to one of which five ml. of fresh skim milk per liter were added just previous to tubing, while in the other the skim milk was already incorporated in dehydrated form. Bacto dehydrated media were used and plates were incubated at 37°C. for 48 hours. With the majority of samples, higher counts were obtained on the media containing sugar than on standard nutrient agar. The use of sugar media did not have as great an effect on total counts when few bacteria were present in the ice cream as when the counts were high. The presence of sugar tended to increase the size of the colonies, decrease the number of pin-point colonies, and give better

84. Abele. 1940. *J. Milk Tech.* 3, 24-32.

85. Robertson. 1936. *Proc. 36th Ann. Conv., Internatl. Assoc. Ice Cream Manfrs.*, 132; *J. Milk Tech.* 2 (1939), 84-86.

86. Foltz and Martin. 1938. *J. Dairy Sci.* 21, 289-294.

agreement in the counts on different dilutions, especially those of 1:1,000 and 1:10,000. There was no significant difference in the total counts on tryptone-glucose-milk agar when the skim milk had been added in different form. A more constant proportion of the bacterial flora in ice cream capable of developing colonies was obtained on standard nutrient agar plus one per cent sucrose and on tryptone-glucose-milk agar than on standard nutrient agar.

Several other media were compared by Babel⁸⁸: (1) tryptone-glucose-skim milk agar, standard nutrient agar plus one per cent sucrose, and standard nutrient agar for determining the total bacterial count of ice cream; (2) brilliant green lactose peptone bile, formate-ricinoleate broth, Leifson's desoxycholate agar, and Bacto violet red bile agar for detecting the presence of the coliform group in ice cream; and (3) for determining the number of yeasts and molds, thermoduric, thermophilic, and spore-forming organisms in ice cream and their relation to the total count. The analysis of 192 samples of commercial ice cream for total bacteria showed tryptone-glucose-skim milk agar to be superior to standard nutrient agar or standard nutrient agar plus one per cent sucrose. Tryptone-glucose-skim milk agar gave higher total counts and colonies of greater size than did the other two media. Standard nutrient agar plus one per cent sucrose gave, on the average, slightly higher counts and colonies of greater size than did standard nutrient agar.

Violet red bile agar was superior to sodium desoxycholate agar in the detection and enumeration of members of the coliform group of organisms on ice cream.

Violet red bile agar and sodium desoxycholate agar are superior to formate-ricinoleate broth or brilliant green lactose peptone bile in detecting the presence of the *Escherichia-Aerobacter* group of organisms in ice cream.

No significant difference was found in a comparison of formate-ricinoleate broth and brilliant green lactose peptone bile in their ability to detect the presence of the *Escherichia-Aerobacter* group of organisms in ice cream.

The most frequent ratio occurring between thermophilic, thermoduric, and sporeforming bacteria in relation to the total count was 1 to 1:10.

Strawberry ice cream contained the largest number of sporeforming organisms when compared with vanilla or chocolate. Chocolate ice cream had the highest ratio of spores to total bacteria, indicating few sporeforming organisms.

A direct relation was secured between the total bacterial count and the yeast and mold count of ice cream. The yeast and mold count usually increased with an increase in the number of total bacteria.

METHODS FOR BACTERIOLOGICAL EXAMINATION OF ICE CREAM

These methods are much like those for the examination of milk. Special attention must be given to the sample since, if it is not representative, results of analysis will be misleading.

88. Babel. 1936. Ice Cream Trade J. 32, 35.

Determination of Streptococci in Ice Cream (Wiley⁸⁹). The method for the detection of streptococci in ice cream has been used by Wiley and his coworkers as follows: The melted sample should be centrifuged for half an hour in a Stewart lactocrite with a speed of approximately 3,000 r.p.m. This apparatus, which consists of a flat aluminum pan holding 20 tubes of one-ml. capacity and stoppered at the outer end with a specially constructed rubber plug, causes the sediment not only to be thrown to the end of the tube but drives it against the rubber plug with such a force that it is almost quantitatively adherent to the plug. Accordingly, if one removes the rubber stopper and by rubbing on a glass slide and over an area of known surface attaches the sediment, one can obtain, on staining and examining the film microscopically, an approximation of the number of organisms and leucocytes in one ml. of the liquid. Because of the debris in the ice cream, which ordinarily renders the usual method of centrifuging milk and cream samples quite impracticable, the above method was resorted to so far as the detection of the presence of streptococci was concerned. It was found eminently satisfactory.

Fay's⁹⁰ Method for Enumerating Bacteria in Ice Cream. Remove and discard a one-fourth inch layer of ice cream from the surface of the container in order to eliminate surface contamination. The sample for analysis is then taken with a sterile butter sampler. The cores should be removed from the entire depth of the ice cream, one from the center and one from the edge of the can. These cores should be placed in a sterile bottle which is submerged in water at 45°C. (113°F.) for five to 10 minutes until the ice cream is melted. A gravimetric sample is then obtained by adding 10 grams of melted ice cream directly to a 90-ml. dilution blank of sterile physiological sodium chloride solution. Appropriate dilutions may then be made from this and plates made in accordance with "Standard Methods for Bacteriological Examination of Milk."

Ellenberger's¹⁴ Method for Determining Number of Bacteria in Ice Cream. Remove the surface of the ice cream to a depth of one-half inch with a sterile spoon and then remove a sample with a sterile butter trier. Transfer the sample to an ordinary dilution bottle and allow to stand at room temperature. Thoroughly mix by shaking and then transfer about one ml. to a sterile weighing bottle and weigh. Dilutions are calculated from this weight and the number of bacteria is expressed per gram.

Newman's⁹¹ Procedures for Bacteriological Examination of Frozen Desserts. The following procedures were developed in a successful system of control of frozen desserts in the State of California over many years.* The former outline of bacteriological technic by Smith, Newman and Nielsen^{91a} is superseded by the present one herein reviewed in some detail; it is an integral part of the regulatory control of these products.

Considerable preliminary work was done in Newman's laboratory to determine whether samples should be gravimetric or volumetric. Since it was found that one ml. of various melted ice creams might vary in weight from 0.5 to 1.5 grams and that the weight of one ml. portion of a sample might vary considerably from weighings of subsequent portions, depending on the temperature at which the sample was held and the interval between weighings, Newman adopted the gravimetric method described by Smith, Newman and Nielsen.

NECESSARY EQUIPMENT

Newman listed several special pieces of equipment besides those usually found in a bacteriological laboratory.

a. Butter boats, made of monel metal, stainless steel, sheet nickel, etc. (one for each sample). Newman uses butter boats made of monel metal supplied by Mojonnier Bros. Company of Chicago.

b. Rimless test tubes 4¾" by 4¾" (one for each sample).

c. Dilution bottles, 6 oz. prescription ovals for the 99 ml. water blanks; the mouths of these bottles have an opening sufficiently large to allow a butter boat to slide freely

89. Wiley. 1912. U. S. Pub. Health Serv., Hyg. Lab. Bull. 41, 251-311.

90. Fay. 1923. J. Dairy Sci. 6, 283-291.

91. Smith, Newman, and Nielsen. 1928. Calif. State Dept. Agr., Mon. Bull. 17, 239-246.

* Newman's paper in which this technic is described contains several illustrations which will not be reproduced in this book.

into the bottle (one required for each sample). Occasionally it may be necessary to alter the width of the butter boat to fit the opening of the dilution bottle. This may be done by squeezing the sides of the boat with pliers.

- d. Water bath for tempering agar medium before pouring.
- e. Suitable analytical balance or scales.
- f. Colony counting chamber with adequate illumination of the Petri dish.

COLLECTION OF SAMPLES

The samples are taken with a sterile metal spatula or spoon. The former is an all metal (one piece) stainless steel, heavily plated dinner knife ground to furnish a blade three to four inches long. The end is square and sharpened in a chisel fashion. Prior to taking each sample, the spatula is washed and then sterilized by heating in the flame of an alcohol lamp. The surface layer of the ice cream is always removed before sampling bulk ice cream because this surface would not be bacteriologically representative of the entire product and, also, because in many instances the surface may be covered with frost crystals which would affect the analysis for fat and solids determinations.

Samples are placed in sterile two-ounce, screw-capped wide-mouth bottles. The aluminum caps of these bottles have lacquered paper liners which are replaced each time the bottles are to be sterilized. This amount of sample has been found to be adequate for both bacteriological and chemical analysis. After the samples have been sealed, and labeled for identity, they are placed in insulated shipping cases containing pads of frozen brine. Samples are thus kept in their original frozen condition despite exterior high temperatures. When the case has been filled it is placed in the hardening room of an ice cream plant over night to refreeze the brine and thoroughly chill the samples. The next morning the brine pads and cover are replaced and the case expressed to the laboratory. Such samples arrive at the laboratory completely frozen even though they may have been shipped hundreds of miles. Included in the shipping case are the inspector's record cards containing all necessary information for the analyst as well as signed statements of the manufacturer that the samples were taken in his presence and in proper manner.

METHOD OF PLATING

1. Each sample is maintained in a frozen condition until ready for plating. Then
2. Samples are placed in a water tempering bath maintained at not more than 40°C., and for a period of not longer than five minutes. As a rule most samples are ready to pipette in from one to two minutes or less. Warming samples to a temperature above 40°C. is unnecessary and should be avoided.

3. When the frozen dessert has melted, shake the sample 25 times in accordance with the directions described for shaking dilution bottles in Standard Methods for the Examination of Dairy Products.

4. Remove the cotton plug from a test tube, holding the tube in a slanting position so that the butter boat slowly slides down toward the opening against the plug. The movement of the boat is controlled by the plug as the latter is withdrawn. Allow about one-half inch of the boat to project out beyond the opening of the tube. Place the tube on one pan of the balance. Discard the cotton plug. Place a counterbalance on the opposite pan and check for exact balance. Add a one gm. weight to the counterbalance.

5. Measure exactly one gm. of the liquid dessert into the butter boat by means of a sterile one ml. pipette. With short practice this may be done very easily, accurately and rapidly.

6. With one hand, remove the wine bottle cap from a 90 ml. dilution bottle. Tilt the bottle slightly to receive the boat. With the other hand, carefully remove the test tube from the balance pan; then using care not to spill any of the sample allow the boat to slide down, end first, into the dilution bottle. Replace the dilution bottle cap. If desired the dilution may be marked with an identification number before proceeding with the next sample.

7. Shake the dilution bottle and then plate according to the method described for milk in the latest edition of Standard Methods for the Examination of Dairy Products.

8. Not more than 25 minutes shall elapse between the time the first frozen sample is placed in the water-bath and the agar medium is poured into the last plate.

9. The temperature and time of incubation of the plates shall be that specified for milk in *Standard Examination of Dairy Products*.

10. In counting incubated plates it is essential to use a colony counting chamber providing adequate illumination from beneath the plate. It is important, also, to use a magnifying glass or hand lens of sufficient power (such as $3\frac{1}{2}\times$ opticians lens) to clearly differentiate between small bacterial colonies and other small objects which may simulate colonies. Particularly is this necessary for some ice milks, some of the mixes and for many of the various ingredients which enter into their manufacture. This subject is treated at some length in the original paper.

11. Counts shall be reported as "Standard Plate Count No., Bacteria Per Gram."

American Dairy Science Association Bacteriological Methods for the Examination of Ice Cream. Through its committee on bacteriological methods the American Dairy Science Association formulated a complete set of bacteriological procedures useful in controlling the quality of dairy products. A preliminary report⁹² was published for ice cream; parts of this report are reproduced below with permission of the chairman of the committee. The complete report should be available to all analysts concerned with the bacteriological examination of ice cream.

Sampling. The sample may be either weighed or measured. The gravimetric method was recommended for research and public-health work.

Media. The media recommended by the committee for ice cream analysis were the standard agar, preparation of which is described in *Standard Methods of Milk Analysis of the American Public Health Association*, and Ayers and Mudge's milk powder agar, which is described in Chapter 26.

Making the agar plates. After placing one ml. of the desired dilutions in Petri dishes, 10 ml. of agar should be admitted to each plate under aseptic conditions. If the agar is in flasks, care should be taken to pour the same amount of agar into each plate. The number of plates poured will depend upon the accuracy desired. Ordinarily, duplicate plates should be prepared from each dilution, although this may not be necessary in routine work.

Incubation. The *Standard Methods of Milk Analysis* recommends incubation of plates for 48 hours at $37^{\circ}\text{C}.$ ($98.6^{\circ}\text{F}.$); still other laboratories use one-week incubation at room temperature. If results are to be compared with the results of another laboratory, the incubation time and temperature should be the same in both laboratories.

Plates should be inverted during incubation to prevent spreaders. The atmosphere in the incubator should be kept moist so as to prevent the drying of the media. Care should always be taken not to stack plates in piles of more than three, in order to insure equal incubation of all plates. Plates should not be disturbed during incubation otherwise the water of condensation will flow across the plate and cause growth on the surface of the agar.

Counting the colonies. A convenient method of counting the colonies is to invert the plate and mark each colony with ink or a wax pencil as it is counted, at the same time keeping count with a tally meter in the other hand. This method greatly increases the accuracy of counting by preventing confusion of the count, owing to interruptions or to counting the same colony twice. All plates in a series should be counted at as nearly the same time as possible. After counting the colonies with the naked eye, all plates should be carefully examined with a hand lens ($3\frac{1}{2}\times$) to detect colonies too small to be seen with the naked eye. Occasionally, it may prove necessary to examine the plates under the low power of a compound microscope to determine the true nature of apparent colonies.

Bacteriological Methods of Examination of Frozen Desserts Recommended by the Ordinance and Code of the United States Public Health Service.³ These follow quite closely those recommended in the milk ordinance and code, parts of which are reviewed

92. J. Dairy Sci. 10 (1927), 460-478.

* Bacteriological Methods of Examining Ice Cream. Jour. Dairy Science. 10 (1927) 460-478

earlier in this book. In this ordinance a grading period is not longer than six months. During this time at least four samples of frozen desserts and pasteurized mix from each plant are collected. Samples from retail vendors may be examined as often as desired. These samples must be protected from contamination and kept below 10°C. (50°F.) until examined. Bacterial plate counts and microscope counts are to be made in conformity with *Standard Methods for the Examination of Dairy Products* of the American Public Health Association. The 1934 edition, instead of the current one, is indicated because of lack of information on applicability of the tryptone-dextrose-skim milk agar as a plating medium in place of the older standard agar medium. Until this question is settled the 1934 *Standard Methods* is to be used.

The Ordinance and Code Recommended by the United States Public Health Service prescribes as follows for bacterial examination of frozen desserts:

"Reporting bacterial plate counts. The number of routine samples which must be examined in many cities makes the use of more than two dilutions per sample impracticable. For this reason it has become general practice to make only two dilutions. In all except known high-count milk or frozen desserts the dilutions used are 1-100 and 1-1,000; on the latter 1-1,000 and 1-10,000. The following special rules for reporting counts are now being used:

"(1) When the higher plate count is more than twice the lower, record the lower count.

"(2) When the higher plate count is not more than twice the lower, apply the *Standard Methods* rules for counting, which may be summarized as follows: (a) If there are plates with 30 to 300 colonies, use all of them and no others; (b) otherwise use that nearest 300.

"(3) In case one plate cannot be counted because of a spreader covering more than half the plate, the result is to be reported as unsatisfactory unless the count of the other plate is within the grade then held by the supply in question.

"(4) Report bacterial plate counts to the nearest 1,000, unless the count exceeds 100,000, in which case report to the nearest 10,000, or unless the count exceeds 1,000,000, in which case report to the nearest 100,000.

"(5) If all plates show no growth the result shall be reported as unsatisfactory.

"A good method by which control officials may judge laboratory technique and the correctness of reporting is to have the laboratory enter its results upon the following form of laboratory record form.

"The State representatives should determine the following data each grading period as a part of the State records:

"(1) Average of the count ratios of those samples for which both dilutions show between 30 and 300 colonies. This should not be over 2.0.

"(2) Per cent unsatisfactory counts (spreaders). This should not be over 2 per cent.

"(3) Per cent incorrectly recorded counts. This should be practically 0.

"These three figures are measures with which to judge the work of the laboratory.

"All counts should be recorded on the ledger record as soon as reported by the laboratory.

"Averaging bacterial counts. In determining grades (or compliance with the minimum requirements) of milk supplies and frozen desserts manufacturers, the average of the last four consecutive counts or reductase hours is used because less than this number has been found by experience not to give a dependable picture of the bacteriological conditions of a supply. The averaging of bacterial counts under this ordinance is done by the logarithmic instead of the arithmetic method. This is because the arithmetic method is sometimes unfair to the manufacturer or producer. Suppose, for example, the laboratory reports the last four consecutive counts to be 10,000, 10,000, 10,000, and 1,000,000. The one unusually high count may have been the result of accident and is not fair cause for degrading or permit revocation, yet if an arithmetic average is used, the supply would not comply with grade A standards, although its most usual quality is grade A.

"For this reason the logarithmic average bacterial count is specified in connection with the enforcement of this ordinance. By its use high counts are "snubbed," so to speak, unless all counts are high, in which case the snubbing effect tends to disappear and the logarithmic average approaches the arithmetic average. For example, the same counts previously listed would yield a logarithmic average of 32,000, thus keeping the supply in grade A, where it obviously belongs.

"*How to find the average bacterial count by logarithms.* The logarithms of bacterial counts from 1,000 to 300,000,000 are given in the table on the following page.⁹³ The logarithms should be entered opposite the counts in the control ledger. To find the average bacterial count find the average of the logarithms and then find the bacterial count in the table⁹³ which is opposite the average logarithm.

Following is an example:

Counts	Logarithms
35,000	4.54
11,000	4.04
9,000	3.95
95,000	4.98
	4 17.51
	4.38 = average logarithm

4.38 in the table is opposite 24,000, which is therefore the average bacterial count.

"If it is found that the average logarithm occurs opposite more than one bacterial count in the table, take the lowest bacterial count as the average.

"*Reductase test.* When the reductase test is used the procedure shall be as follows: Follow Standard Methods except that samples are to be examined at the end of each hour but not beyond 8 hours. The reduction time shall be expressed as the number of elapsed full hours when decolorization is first observed. Samples not reduced at the end of 8 hours are to be reported as reduced in 9 hours. For purposes of grading the simple arithmetic average (not the logarithmic average) of the last four consecutive samples is to be used.

"*Bacterial and reductase test standards.* Section 7 of this ordinance establishes limits of average bacterial plate count in the case of frozen desserts, pasteurized mix, and pasteurized or otherwise heated ingredients derived from milk, and of average plate count or average direct microscopic count or average reduction time in the case of raw ingredients derived from milk. When average direct microscopic counts are used the limits are the same as for average plate counts if clumps are counted, but four times as high if individual organisms are counted. The limits are doubled for cream used as an ingredient of frozen desserts."

American Public Health Association Procedures for Determining the Number of Bacteria in Ice Cream. These are embodied in *Standard Methods for the Examination of Dairy Products*, a new edition of which is published at intervals of a few years. The agar plate method of making counts for routine control of frozen ice cream is recommended. Where it is possible, the microscope method is also recommended to give results with which to supplement the plate counts. Detailed procedures are given for handling the sample. These will not be recorded here for most of them would be used only by an analyst who has the right to be making such analyses.

The plating medium recommended is tryptone-glucose-skim milk agar, unfortunately designated as "nutrient agar," the name used for the plating medium for many years. The agar recommended in the 1939 edition of *Standard Methods for the Examination of Dairy Products* is the new medium approved for milk analysis. The Advisory Committee which prepared the Frozen Desserts Ordinance and Code Recommended by the United States Public Health Service, May, 1940 Edition, indicated that in enforcement of that ordinance, the old plating medium should be used. Consequently, they advised use of the 1934 edition of *Standard Methods of Milk Analysis* until it could be determined whether new standards would have to be established.

93. In the printed ordinance is a table to be used for computing logarithmic averages of bacterial counts.

Alternative Bacterial Standards Established by Section 7 for Frozen Desserts, Pasteurized Mix, and Ingredients Derived from Milk

Product, heated or unheated, grade of plant ⁹⁴	Log. average plate count not to exceed	Log. average direct microscopic count not to exceed		Arithmetic average reductase hours not less than
		Clumps	Individual organisms	
FROZEN DESSERTS AND PASTEURIZED MIX				
Grade A plants.....	50,000
Grade B plants.....	100,000
Grade C plants.....	No limit
CREAM AS INGREDIENT				
<i>If pasteurized:</i>				
Grade A plants.....	100,000
Grade B plants.....	500,000
Grade C plants.....	No limit
<i>If raw:</i>				
Grade A plants.....	400,000	400,000	1,600,000	5
Grade B plants.....	2,000,000	2,000,000	8,000,000	2½
Grade C plants.....	No limit	No limit	No limit	No limit
MILK AND INGREDIENTS DERIVED FROM MILK				
<i>If pasteurized, condensed, powdered, etc.:</i>				
Grade A plants.....	50,000
Grade B plants.....	250,000
Grade C plants.....	No limit
<i>If raw:</i>				
Grade A plants.....	200,000	200,000	800,000	6
Grade B plants.....	1,000,000	1,000,000	4,000,000	3½
Grade C plants.....	No limit	No limit	No limit	No limit

94. The Grade A specifications listed here are identical with the minimum requirements in the non-grading form of this ordinance.

Fabian's ⁹⁵ Microscope Method for Counting Bacteria in Ice Cream. The only additional apparatus required is an analytical balance. Slides used in this work should be exceptionally clean if the best results are to be obtained. The slides are placed on the balance and counterpoised; .01 gram of ice cream is then weighed upon each end of the slide as quickly as possible in order to reduce the error owing to evaporation. A platinum loop has been found to work very well for putting the ice cream on the slide. The .01 gram of ice cream is then spread uniformly over an area of one square centimeter, using a clean needle. This area may be conveniently measured by placing the slide upon the guide plate or any surface ruled in square centimeter areas. After the film is spread, the slide should be placed upon a warm surface for drying. The drying should not be too rapid for this may crack the film and cause it to peel from the slide. However, the drying should be completed quickly (within 10 minutes) or growth may take place.

After the film has been prepared as above described, the slides are ready for the staining process. They are first dipped in xylol or other suitable fat solvent for five minutes to remove the fat. Longer exposure is necessary for ice cream than for milk, owing to the larger amount of fat present. The xylol is then drained off and the slide again placed on a warm surface to evaporate the remainder of the xylol. The slides are next immersed in 70 to 95 per cent grain or denatured alcohol for about 20 minutes.

95. Fabian. 1925. J. Dairy Sci. 8, 246-269.

The alcohol is poured off and the slide again placed on a warm surface. The film is then stained 30 seconds with Loeffler's methylene blue, prepared as follows: saturated alcoholic solution of methylene blue, 30 ml. caustic potash (.01 per cent solution), 100 ml. Care should be taken in selecting the methylene blue. Fresh preparations of the stain from a satisfactory source should be used.

The film is then ready to be decolorized. This may be done by first draining off the excess stain, and placing the slide in 70 to 95 per cent alcohol. The length of time it should remain in the alcohol is a matter of judgment and experience; usually dipping the slide in and out once or twice is sufficient. In case the decolorization is carried too far, the preparation may be re-stained without apparent injury. The film should be warmed again after it has been decolorized; this seems to be necessary for best results.

In routine practice staining jars may be used to good advantage. Place four jars in a row, containing xylol, 95 per cent alcohol, Loeffler's methylene blue, and 95 per cent alcohol, respectively. The preparation of four slides may be started and carried through the whole procedure at the same time, and these followed by four more, thus saving considerable time.

The Frost Little Plate Method for Counting Bacteria in Ice Cream. This technic described fully on page 354 was observed by Bryan *et al*^{95a} to yield counts comparable to those obtained with the standard agar plate.

Fay's⁹⁶ Microscope Method for Examination of Ice Cream and Other Dairy Products. This is another modification of the microscope method for counting bacteria in dairy products. Fay believed that the weighing procedures involved in securing .01 gram of sample on a slide, as proposed in the Fabian method reported above, introduced possibilities for error besides being too tedious and time consuming for practical conditions. Fay, therefore, placed .1 ml. of the sample on a clean slide and added two to four drops of sterile water. The mixture was then spread evenly over the entire surface of the slide. The film was allowed to dry and was then stained in the usual manner. If the diameter of the microscope field has been standardized to .157 mm. the bacterial count may be determined by multiplying the average number of cells per field by the factor 1,000,000.

Examination of Ice Cream by the Burri Film Technic. Results of examination of several other dairy products with Burri's⁹⁷ method are given in other places in this book. Long and Hammer⁹⁸ applied it to ice cream.

Small portions (.02 mg.) selected from firm ice cream are spread over the surface of a dry agar slant using a low-power binocular microscope to aid in keeping the portions of fairly uniform size and to avoid scraping from a large area. The number of colonies developing from the various portions indicates the distribution and general bacterial content. Variation in the weights of the portions picked is greater than with butter. The data list the number of colonies on agar slants smeared with the interior of package ice cream, interior and surface of dipped ice cream including those with counts over 100,000 per ml., and a comparison of the counts on ice cream by this Burri technic and the plate method. There was no close agreement between the two methods, counts being generally higher with the Burri technic. The primary advantage of the Burri technic is the use of few slants and the opportunity to study distribution of the organism in the product.

Bacterial Standards for Ice Cream. These are largely plate counts and in the past have varied widely. Efforts have been made to relate plate counts to conditions of production. While such a relationship may exist under some conditions, it may have no such relationship under other conditions. In some cases, it seems that about all plate counts are good for is to confuse an ice cream manufacturer and make him believe that his

97. See Chapter 6 for discussion and references.

98. Long and Hammer. 1940. *Iowa State Col. J. Sci.* 14, 163-177.

product may have too many microorganisms with no effort whatever to find out what they are and whether they have any significance. *Standard Methods for the Examination of Dairy Products*, 1939 edition, in a discussion "Interpretation of Agar Plate Counts" covers these points quite well. In one place it is stated:

"In this connection it should be borne in mind that there is an unavoidably high percentage of error in the agar plate method of estimating the number of bacteria in ice cream; also that ice cream having a high plate count does not necessarily contain pathogenic bacteria; and that an ice cream having a low agar plate count is not necessarily free of pathogenic bacteria. Laboratory analyses should always be combined with sanitary inspections before definite conclusions are drawn."

It is also stated that a high count in ice cream means not necessarily an insanitary product but more properly a neglected product. This is not necessarily true, for the committee which prepared these "standard methods" has admitted that there is "an unavoidably high percentage of error in the agar plate method of estimating the number of bacteria in ice cream."

The whole question is whether bacteria plate counts are indices of quality. What is "quality" in ice cream? Nothing more than excellence of character which involves many factors. Bacterial content is only one of them and, at best, is of questionable value in some cases.

Many standards have been proposed for so-called control of ice cream. They vary widely as do most such standards for other dairy products. *Standard Methods for the Examination of Dairy Products*, while giving seven pages of instructions for ice cream analysis which are offered as "standard methods," makes no suggestions as to "standards." Some of the difficulties in establishing such standards have been reviewed by Anderson,⁹⁹ who was not opposed to them but believed that they had great limitations and must be used most carefully. They will not guarantee freedom from pathogenic bacteria but may contribute to a more hygienic product when used along with other proposals which were made. Bardsley¹⁰⁰ recognized two grades of ice cream designated as A and B. To qualify as Grade A, coliform bacteria must be absent in .1-ml. amounts and the total number of bacteria shall not exceed 200,000 bacteria per ml. at 22°C.(71.6°F.) or 37°C.(98.6°F.); enterococcus must be absent in .01 ml. and spores of *Clostridium welchii* must be absent in 10 ml. For Grade B ice cream the requirements are absence of coliform bacteria in .01 ml., not over 500,000 bacteria per ml., absence of enterococci in .01 ml., and absence of enterococci in 10 ml.

In 1932, Fabian¹⁰¹ reported a range of 100,000 to 800,000 per gram. He considered a standard of 100,000 per gram as a reasonable bacterial standard. This was supported by experience in ice cream plants of varying sanitary conditions. As chairman of the Committee on Ice Cream Sanitation of the International Association of Milk Santarians¹⁰² Fabian

99. Anderson. 1935. J. Roy. Sanit. Dist. 55, 592-599.

100. Bardsley. 1938. J. Hyg. 38, 527-546.

102. Fabian (Chairman). 1939. J. Milk Tech. 2, 193-196.

studied the standards of 12 states. They varied from 75,000 per gram in California to 500,000 per ml. in two other states. In the case of one state the standard is 100,000 per ml. for plain and 500,000 per ml. for frozen desserts with fruits and nut meats. The reason for such standards is not easy to see. If plate counts mean anything at all in ice cream sanitation, why should there be leniency with a nut and fruit product, especially when Tracy and Prucha¹⁰³ found that 50 per cent of samples of nut meats harbored *Escherichia coli*? Newman⁹¹ stated that the first standard in California was not more than 150,000 per gram but in August, 1937, it was reduced to 75,000 per gram and the law was broadened to include sherbets.

Graaff¹⁰⁴ reported the requirements of the ice cream decree, based on the Netherlands food law to be: negative Storch reaction; no more than 100,000 organisms per ml.; and no viable coliform bacteria in .1 ml. or less. The vanilla ice cream for sale in Utrecht gave the Storch reaction in 25 per cent of cases, about 35 per cent of the tested samples had more than 100,000 organisms per ml.; and about 46 per cent had a coliform titer of .01 to .001 ml. The streptococcus titer, useful in indicating age of ice cream and care taken in preparation and storage, was determined, results indicating that for ice cream of good quality the titer should not be more than .001 ml.

In England, Benson¹⁰⁵ suggested both chemical and bacteriological standards for ice cream as follows: Bacteriological—(1) not more than 100,000 bacteria per ml. and no coliform bacillus in .1 ml., also all ice cream mixes must be subject to efficient pasteurization. Chemical—(1) ice cream to contain not less than six per cent butterfat and not less than 18 per cent milk solids total. A standard of not over 100,000 colonies per ml. was also approved by Thomas *et al.*¹⁰⁶ He also believed that coliform bacteria should not be present in .1 ml.

The United States Public Health Service,³ in its frozen desserts ordinance which is recommended for adoption to states and communities, prescribes limits of bacterial content of frozen desserts of 50,000 per ml. of melted product for Grade A plants, 100,000 per ml. for Grade B plants, and no limits for Grade C plants. These standards are significant, for they are used with careful plant inspection. This ordinance is probably the best statement of procedures which should be followed in making certain that proper products are distributed to the consuming public. Fabian¹⁰¹ stated many years ago that whatever method is adopted for this purpose it should

1. Be concerned with the type of raw materials;
2. Refuse to permit reprocessing of ice cream mix;
3. Define pasteurization as at least 65.6°C. (150°F.) for 30 minutes;

4. Provide a maximum standard of not over 100,000 bacteria per gram;
5. Prescribe medical examination of all who handle the product;
6. Require licensing of manufacturer after inspection;
7. Provide for regular inspection.

England¹⁰⁷ and Anderson⁹⁹ believed that inspections of methods of manufacture were very important. Their suggestions were quite similar to those quoted above from Fabian. Anderson recommended pasteurization at 71°C. (160°F.) and storage of the mix before pasteurization below 4.44°C. (40°F.) for not over two days.

Sediment Tests on Frozen Desserts. The sediment testing of milk and butter has been generally accepted. This test has done much to improve the products just mentioned. Appearance of dirt on a disc is visual evidence that anyone must admit. One important objection is that straining may be resorted to to remove the visible dirt. This was also admitted in *Standard Methods of Milk Analysis* of the American Public Health Association. Parker¹⁰⁸ recommended that a half-pint sample of mix or frozen dessert be used in the sediment test. Detailed instructions were prepared by a joint committee of the American Public Health Association¹⁰⁹ for determining sediment in various constituents of frozen desserts.

Coliform Bacteria in Frozen Desserts. Attempts have been made to determine the value of coliform bacteria content with nearly all dairy products. While these organisms have been found in ice cream, little agreement exists as to their significance. Examination of results of many investigations on this question probably indicate that the coliform test alone is not acceptable.

Ayers and Johnson⁷⁵ found organisms forming gas from lactose present in one-tenth ml. in 88.33 per cent of 120 samples of ice cream. The average number of gas formers in the entire series of samples was 16.298 per ml. Ellenberger¹⁴ made plates with ice cream samples with Endo's medium, since the presence of *Escherichia coli* in dairy products has been looked upon with suspicion. This technic indicated no increase in members of the *Escherichia coli* group, but on the contrary a decided falling off during storage. Rawlinson⁶⁴ found 22 samples of ice cream in London which contained over 10,000 coliform organisms per ml. while *Clostridium sporogenes* was present also in large numbers. This investigator believed that the presence of so many coliform organisms was a danger signal. The *Escherichia coli* count of ice cream was believed to be specific in indicating unsanitary conditions of manufacture by Weinzirl and Harris.⁷⁹ It is doubtful whether *Escherichia coli* could have more significance in ice cream than it has in milk. Until that question is settled, the use of *Escherichia coli* as an index of unsatisfactory conditions in ice cream manufacture is open to considerable question. This position seems to be justified by data

108. Parker. 1939. J. Milk Tech. 2, 87-90.

109. Amer. Pub. Health Assoc. Yearbook, 1937-1938, 49-51.

110. Anzulovic. 1932. J. Bact. 23, 56.

reported by Fabian and Coulter.⁴⁸ Anzulovic¹¹⁰ attempted to determine whether *Escherichia coli* could survive in ice cream. Seventy-three samples of ice cream were found to contain from 200 to 157,000 bacteria per ml. in some of which *Escherichia coli* was present. Two cultures of *Escherichia coli* survived 62.8°C.(145°F.) in milk and 13 survived 62.8°C. in ice cream mix. At 65.5°C.(150°F.) one culture survived three out of four trials and at 68.3°C.(155°F.) the same culture survived one out of four trials. The ingredients of the mix, especially the sugar, showed some preservation action on the microorganisms.

In order to have more information on heat resistance of coliform bacteria in ice cream, Myers and Sorensen¹¹¹ considered it desirable to establish the thermal resistance in ice cream for especially resistant strains of organisms within the coliform group. Two different strains of *Escherichia coli* and one of *Aerobacter aerogenes* were used. One strain of *Escherichia coli* survived for a period of 20 minutes at 60°C.(140°F.) and for five minutes at 62.8°C.(145°F.). The strain of *Aerobacter aerogenes* survived 10 minutes at 140°F. and for five minutes at 145°F. Neither organism would, therefore, survive pasteurization at 140°F. for 30 minutes. However, the second strain of *Escherichia coli* was much more heat resistant. It survived for 118 minutes at 60°C.(140°F.), for 55 minutes at 62.8°C.(145°F.), for 24 minutes at 65.6°C.(150°F.), but for only 9.5 minutes at 68.3°C.(155°F.). On the basis of these results a pasteurization temperature of 68.3°C.(155°F.) for 30 minutes is recommended to insure complete destruction of coliform bacteria in ice cream mix. Aging ice cream mix at 7.2°C.(45°F.) for 24 hours had no appreciable effect on the thermal resistance of *Escherichia coli*. In a discussion of the work by Myers and Sorensen, Parfitt reported results which he had collected at Purdue University. Sixty-seven cultures of *Escherichia coli* and *Aerobacter aerogenes* were selected and pasteurized in ice cream in capillary tubes. No coliform organisms were found which survived 62.8°C.(145°F.) for 30 minutes. Stark and Patterson,¹¹² who isolated 505 pure cultures of coliform organisms from water, also found that all the organisms isolated were destroyed at 62.8°C.(145°F.) for 30 minutes.

Results of Myers and Sorensen show clearly the need for uniform regulations as to time and temperature of pasteurization of ice cream mixes. If mixes are pasteurized at 68.3°C.(155°F.) for 30 minutes and coliform organisms are found in the finished products, more accurate interpretation can now be placed upon these results than was possible previously. Paley and Isaacs¹¹³ found a strain of *Escherichia coli* to be about twice as resistant to heat in ice cream mix as in milk.

To secure information on the significance of the presence of coliform bacteria in ice cream, Yale¹¹⁴ studied the quality of bulk ice cream sold in Geneva, New York. The count of coliform bacteria proved to be a

fairer measure of quality than the standard plate count since the freshly pasteurized mix in practically all cases was free from coliform organisms. Thus, the presence of coliform organisms is primarily an index to handling of the product subsequent to pasteurization. Discriminating manufacturers should include tests for coliform organisms in finished products since their presence is always undesirable and indicative of some faulty condition. Relatively high coliform counts in the case of ice cream with low-standard plate counts are significant, and line-run samples will usually show contamination either from ingredients or from equipment. The coliform plate count is more sensitive in detecting contamination from the vendor's dipper than is the standard plate count.

Since there are instances where total counts indicate faulty conditions but coliform counts do not, a test for the coliform group should supplement rather than supplant the standard plate count. In discussing Yale's work, Fay stated that coliform counts have some value as an index to pasteurization efficiency, especially if high temperatures are employed. If the usual thermal exposure of 62.8°C.(145°F.) for 30 minutes is employed, the interpretation of the test must be made with caution. The test has some value as an index to the contamination of ice cream subsequent to pasteurization, especially if the freshly pasteurized product is known to be free from colon types. Tests for coliform bacteria, Yale believed, serve as an index to the general sanitary conditions surrounding production of ice cream; in this capacity he believed it to be a poor substitute for the bacterial plate count. Yale thought that the coliform test had special merits for demonstrating contamination of small magnitude, such as from the ice cream scoop.

Thomas, Jenkins, and Evans¹⁰⁶ also believed that coliform bacteria had value in bacteriological ice cream analysis and that they should be absent in ice cream in .1-ml. amounts. That it may be present in large numbers in some samples was shown by Fournelle and Macy.^{114a}

Carbonated Ice Cream. The freezing of ice cream with incorporated carbon dioxide instead of air, was proposed by Heath¹¹⁵ who claimed the following advantages:

1. Carbon dioxide is cleaner than air.
2. Vitamins are destroyed by oxidation. Carbon dioxide protects the vitamins.
3. Carbon dioxide is not a flavor saver but a flavor intensifier.
4. Ice cream with incorporated carbon dioxide replacing the air "becomes atmospherically compressed to a greater degree during hardening than ordinary ice cream."
5. A volume of carbon dioxide in Heathized ice cream requires over 35 per cent more heat to raise it one degree than a similar volume of air.
6. The employment of carbon dioxide is imitating nature more closely than to imprison air in foods.

These claims naturally caused scientific investigations to be instituted to determine their validity. Prucha, Brannon, and Ambrose¹¹⁶ studied the

114a. Fournelle and Macy. 1912. *J. Dairy Sci.*, 25, 475-487.

116. Prucha, Brannon, and Ambrose. 1922. *Ill. Agr. Expt. Sta. Circ.* 256.

effect of carbon dioxide on the bacterial life in carbonated ice cream. One lot of freshly frozen ice cream prepared from a mix having 620,000 bacteria per ml. had 703,000 bacteria per ml. in the plain mix and 765,500 per ml. in the carbonated cream. At the end of 58 days, there were 530,000 in the plain and 742,000 in the carbonated products. A sterile ice cream mix was also seeded with typhoid bacilli so that each milliliter had 24,700,000 cells. Counts were made for 12 days. The results are tabulated below:

Samples	Plain ice cream	Carbonated ice cream
Mix.....	24,700,000	
Freshly frozen.....	50,050,000	50,700,000
5 days old.....	8,180,000	9,380,000
12 days old.....	10,465,000	6,896,000

The National Association of Ice Cream Manufacturers also had an investigation made for them by Rettger of Yale University. Rettger¹¹⁷ could find no evidence that carbon dioxide exerted bactericidal action in ordinary commercial ice cream. With *Bacillus cereus* in ice cream, there was a more pronounced decrease in numbers than in the plain ice cream. Rettger explained this on the basis of the extreme susceptibility of this organism to increased acidity. The process, however, could not be regarded as making ice cream safer. Winslow, in the same report, presented experimental data to show that carbonation, according to the Heath process, did not materially affect the rate of melting of ice cream. Smith of Yale University could find no evidence that carbon dioxide in ice cream preserved the vitamins.

The proposal that ice cream was badly contaminated by the incorporation of foul air into it caused Fabian³³ to study the question. Fabian found that, contrary to the prevailing opinion that large amounts of air entered the freezer, only very little entered. He found that bacterial contamination from the air was insignificant. Fabian found a considerable variation in the bacterial content throughout the year. The argument, then, for substitution of the air with inert gases is groundless.

Survival of Pathogenic Bacteria in Ice Cream. Epidemics caused by ice cream and survival of pathogenic bacteria in it have been discussed in the author's *Food-Borne Infections and Intoxications*. They will not be discussed here. While freezing may greatly reduce the viable bacteria in ice cream, the product is by no means sterilized. Pathogenic bacteria may live for a long time, far beyond the time that the product would ordinarily be stored. It is necessary, then, to keep the ingredients clean and free from suspicion. This is borne out by the number of outbreaks of communicable diseases caused by ice cream.

CHAPTER 11

MICROBIOLOGY OF CONCENTRATED MILKS

Various types of concentrated milks are now widely used. Extraction of water and the processes which are used to remove it, cause these various products to differ greatly in appearance. These concentrated products owe their reputation to the fact that they may be kept for long periods under proper conditions.

The Standard of Identity ¹ for sweetened condensed milk is as follows:

Sweetened Condensed Milk—Identity. (a) Sweetened condensed milk is the liquid or semi-liquid food made by evaporating a mixture of sweet milk and refined sugar (sucrose) or any combination of refined sugar (sucrose) and refined corn sugar (dextrose) to such point that the finished sweetened condensed milk contains not less than 28.0 per cent total milk solids and not less than 8.5 per cent of milk fat. The quantity of refined sugar (sucrose) or combination of such sugar and refined corn sugar (dextrose) used is sufficient to prevent spoilage.

Microbiology of Sweetened Condensed Milk. Much has been published on this subject, but it is not always easy to determine just what type of product was used; consequently, the results reported by different investigators ought not to be compared too closely. Much of the work on the microbiology of condensed milk has been done on swelled or otherwise spoiled cans, and far less on cans which could be considered to be normal.

One of the first reports indicating that condensed milk was not sterile was by Kossowicz,² who isolated *Bacillus sinapinagus*, *Pseudomonas fluorescens*, and *Serratia marcescens*. The next year Dold and Stewart³ reported from 700 to 120,000 bacteria per ml. in eight samples of full cream, and 10 of machine-skimmed sweetened milk, purchased on the open market. Streptococci were isolated from eight specimens. *Clostridium sporogenes* and *Escherichia coli* were absent. Attempts to demonstrate the presence of *Mycobacterium tuberculosis* were not successful. Non-heat-resisting forms were found in condensed milk by Klein⁴ also. Eight samples, discussed in his first report, showed the presence of Micrococci. In the second report all of the 32 shop samples of 11 different brands were reported to contain from 13 to over 2,000 bacteria in one-tenth gram, a rather large number; all but four contained Streptococci in one-tenth gram, and 14 showed the presence of gas-forming aerobic bacteria (Savage and Hunwicke⁵). Large numbers of bacteria were also observed by Heggs⁶ in 11 samples purchased on the open market. The counts varied from 230 to 70,490 per ml. on gelatin. Streptococci were found in all specimens of condensed milk examined by Gordon and Elmslie.⁷ They

were not identified. From their experimental data, it is probable that *Escherichia coli* was present. *Proteus* organisms were found in three samples. Andrews⁸ believed that organisms multiplied in condensed milk, and that a few survivors might mean many hundreds later. It is interesting to note that many of the viable bacteria in condensed milk are nonsporeforming species. That the condensing process affects the bacterial population seems to be borne out by the investigations of Delepine⁹ and Ruehe.¹⁰ Delepine observed that a bacterial content of 38,000,000 bacteria might be reduced to less than 50. *Mycobacterium tuberculosis* was apparently destroyed, because the finished milk failed to produce lesions in guinea pigs when it was inoculated into them. Continuous observations were made by Ruehe during the condensing process. Bacterial counts were made of the raw milk, and of the processed milk after preheating, concentration, and superheating. Some of the samples were modified by skimming, by the addition of some concentrated milk, and by changes in other conditions. The results showed that the processes through which milk goes in being condensed, tend to lower the bacterial content of the finished product, the maximum, minimum, and average final counts being, respectively, 36,400, 480, and 6,289 bacteria per ml., though the initial milk had counts in some cases of over 100,000,000. High bacterial counts in condensed milk are suggested as due to contamination after manufacturing or to improper storing.

The lower bacterial content of condensed milk was due to longer process times and higher temperatures by Park, Schroeder, and Bartholow.¹¹ They were of the opinion that inferior grades of milk were frequently used for condensing. Bacteria were found in all of 85 cans of condensed milk, the number varying from 500 to 8,000,000. *Escherichia coli* was present in eight of 17 brands. Thirty brands of Japanese condensed milk, examined by Nishizaki and Wakita,¹² were found to be free from *Escherichia coli*. Beveridge,¹³ when investigating the keeping properties of condensed milk in the tropics, reported that increase of acidity by bacterial fermentation may enhance the change of color. Sporeforming bacteria were said to be the cause of the trouble. Weinzirl,¹⁴ in his investigation of the bacteria in various canned foods, included a few cans of milk. Twelve cans were examined, of which 10 were not sterile. The organisms which were isolated were aerobic sporeformers (*Bacillus mesentericus* and *Bacillus subtilis*). Haarnagel¹⁵ made colony counts on 48 samples of condensed milk from America, Germany, Denmark, and Switzerland. The colony counts varied from 0 to 242,000 per ml. Only one can was sterile. Both sporeforming and nonsporeforming bacteria were found. Attempts to show the presence of tubercle bacilli were not successful.

One of the most complete investigations and discussions of the microbiology of sweetened condensed milk was published by Savage and Hunwicke.⁵ They worked with English, American, and Canadian brands. All of their samples were full cream, and none were of the machine-skimmed variety. Of 15 market samples and 34 factory samples which were sound or not known to be spoiled they found great variations in bacterial content. For instance, one can, packed in the United States, had a count of 100 and 175 colonies per gram, while another specimen showed 400,000 and 460,000 per gram. According to Gehri,¹⁶ Swiss condensed milk is not sterile, but may contain as many as 9,000 cells per ml. Haarnagel¹⁵ reported many bacteria in condensed milk from Germany, America, Denmark, and Switzerland. Thus condensed milk, packed in various countries, seems uniformly to contain many bacteria. However, it should be pointed out that since these investigations were reported, the entire subject of processing canned foods has been studied and procedures perfected. It is probable that the situation with respect to viable bacteria is quite different today. Greater attention is also paid to sanitation in food preservation. This means a smaller bacterial load imposed on the process. Such a situation seems to be borne out by the results of a bacterial examination in the author's laboratory of 300 cans of condensed milk packed in 1928. The great majority of them were sterile.

Types of Organisms in Sweetened Condensed Milk. Sweetened milk is not always sterile although it probably contains fewer viable microorganisms today than formerly.

Yeasts. Yeasts have been reported by several investigators; Savage and Hunwicke⁵ stated that swelling of cans of sweetened condensed milk was almost invariably due to yeasts. However, the mere presence of yeasts could not be considered as evidence that the cans would swell. The biological properties of the yeasts must be considered. Even the ability of yeasts to grow in 50 per cent sugar solutions is not conclusive evidence that they will cause swells to develop. Savage and Hunwicke's inoculation experiments showed that 70 per cent of the yeasts from swelled cans of milk caused swelling of cans into which they were injected. The factors which seemed to influence yeast growth were sugar concentration (35 to 40 per cent) and oxygen supply.

Gas-Forming Aerobic Bacteria. Savage and Hunwicke⁵ found them present in two normal cans and five swelled cans. The strains which they isolated were *Escherichia coli*. They were not inhibited by the amount of sucrose present. The organism did not grow but ultimately died out. The two strains found in the sound cans were from cans packed by the same factory. The contents of these cans were quite sound, and would probably have remained so and the strains have died out. Nishizaki and Wakita)¹² found 30 samples of Japanese condensed milk to be free from *Escherichia coli*. Certainly a microorganism with such low heat resistance would not, ordinarily, be expected in a food which has been processed.

Aerobic Sporeforming Bacteria. Of the 30 sound cans of sweetened condensed milk examined by Savage and Hunwicke,⁵ aerobic sporeforming bacteria were found in 26. Sixty-three out of 76 total samples showed these organisms. These investigators believed that they would have been found in the rest of the cans if larger amounts had been examined. These forms are, probably, always present, even in sound cans. While they did not ordinarily cause swelling of cans, they were believed to be able to cause decomposition changes. Savage and Hunwicke suggested that these organisms could not grow

16. Gehri. 1928. Mitt. Lebensmtl. Untersuch. u. Hyg. 19, 89-101.

in the milk on account of anaerobic conditions and the concentration of the milk. However, experiments in which air was blown into the milk did not result in growth.

Thayer¹⁷ made a bacteriological examination of samples of condensed milk which had spoiled from 12 to 24 hours after condensing and canning and found *Bacillus subtilis*. A sterilizing temperature of 125°C.(257°F.) for 15 to 20 minutes is recommended where the difficulty is encountered. Delepine also observed sporeforming bacteria in condensed milk.

Thermophilic Bacteria. These bacteria which thrive at high temperatures have been shown to be present in sweetened condensed milk. Weinzirl¹⁴ found a thermophilic organism in one can. Savage and Hunwicke⁵ examined 76 cans of condensed milk and found 36 of them to contain these forms. Of 30 sound cans of milk, 17 contained thermophiles. They found these bacteria as abundant in the commercially sound cans as in the swelled cans. They believed them to be widely disseminated in condensed milk. The characteristics of all of the thermophiles from condensed milk were given in tabular form. All of the strains were sporeformers which did not form gas. The presence of these bacteria in condensed milk would suggest that it should be stored with the same care which is given other foods in which viable thermophiles may grow.

Anaerobic Bacteria. While anaerobic bacteria would be expected in condensed milk, they are conspicuous by their absence. Savage and Hunwicke isolated anaerobic bacteria from only two cans. One came from a can which was slightly swelled; the other came from a can which gave some evidence of fermentation, although Savage and Hunwicke reported that there was no evidence of pressure from gas. Yeasts and gas-forming bacteria were not present. Lack of development of the anaerobe in condensed milk was attributed not to the presence of so much sucrose, but to unfavorable physical conditions consequent on condensation. These investigators mentioned the interesting observation that, although *Clostridium welchii* is present in raw milk, it was not found once in condensed milk. It seemed apparent to Savage and Hunwicke that anaerobic bacteria are not significant in spoilage of condensed milk. Another investigator who isolated anaerobic bacteria was Haarnagel. He isolated anaerobic sporeforming organism which formed butyric acid as well as an anaerobic diplococcus.

EVAPORATED MILK

Evaporated milk is the product resulting from the evaporation of a considerable portion of the water from milk or from milk with adjustment, if necessary, of the ratio of fat to nonfat solids by the addition of, or by the abstraction of, cream. It contains not less than 7.8 per cent of milk fat nor less than 25.5 per cent of total milk solids; provided however, that the sum of the percentages of milk fat and total milk solids be not less than 33.7 per cent.

The Standard of Identity for evaporated milk¹ under the Food, Drug and Cosmetic Act of 1938 is as follows:

Evaporated Milk—Identity—Label statement of optional ingredients. (a) Evaporated milk is the liquid food made by evaporating sweet milk to such point that it contains not less than 7.9 per cent of milk fat and not less than 25.9 per cent of total milk solids. It may contain one or both of the following ingredients: (1) Disodium phosphate or sodium citrate or both, or calcium chloride, added in a total quantity of not more than .1 per cent by weight of the finished evaporated milk. (2) Vitamin D in such quantity as increases the total vitamin D content to not less than 7.5 U.S.P. units per avoirdupois ounce of finished evaporated milk. It may be homogenized. It is sealed in a container and so processed by heat as to prevent spoilage.

Results of many investigations published several years ago indicated a high degree of unsterility in cans of the product. In all probability this

17. Thayer. 1912. Vermont Agr. Expt. Sta. Bull. 170.

is not the situation today because better plant sanitation and better processing have made it possible to destroy microorganisms in canned foods. Gordon and Elmslie⁷ examined four apparently sound cans of unsweetened condensed (evaporated) milk. None of the cans was sterile. *Escherichia coli*, anaerobic bacteria, and streptococci were not found. Aerobic organisms, however, were present. Andrews,⁸ contrary to the data of Gordon and Elmslie, found evaporated milk to be invariably sterile. Thirty-seven cans examined by Park, Schroeder, and Bartholow¹¹ were found to be infected. The lowest number of bacteria found was 300 bacteria per ml. and the highest 50,750 per ml. with an average count of 7,000 bacteria per ml. *Escherichia coli* was present in four cans. Savage and Hunwicke commented on the fact that cans of evaporated milk, containing this lactose-fermenting organism, remained sound. They examined 104 cans of evaporated milk. Eighty-five per cent of the shop samples and 76 per cent of the factory samples were found to be sterile. The organisms were quite diverse in characteristics. All of 25 cans examined by Weinzirl were sterile. These data seem to support the general opinion that evaporated milk is much better bacteriologically than condensed milk. This is due to the fact that the former can be given a cook which is more adequate.

A comprehensive study of 315 presumably sound and 150 presumably defective samples of evaporated milk, 252 samples of sound canned cream, 115 specials, and 80 samples of sweetened condensed milk was made by Nichols.¹⁸ Of the evaporated milk samples presumably sound only 16 or five per cent were not sterile; with the defective cans 59 were not sterile (39 per cent). Canned cream presumably sound showed 50 (20 per cent) not sterile and the specials, selected for some abnormality, showed three per cent not sterile. The non-sterile sound (commercially sterile) tins of cream were mostly associated with the introduction of large 12-ounce cans. Spoilage caused by nonsporeformers was generally shown by a blown condition (here called "swells"), or by curdling or by both together. Many kinds of bacteria were isolated but strains of the genus *Escherichia* were the commonest producers of gassy spoilage. Aerobic sporeformers were isolated in about 80 cases from both sound and unsound cans. Of these 69 per cent were *Bacillus subtilis* strains and 15 per cent were *Bacillus licheniformis*. Some were associated with spoilage, clot, bitter flavors, etc., but others were from apparently sound tins. Cans inoculated with these strains showed in some cases no defects even up to 18 months; in others, defects appeared. A bitter flavor associated with thinness developed in some cases. Aerobic sporeformers were isolated from both evaporated milk and from canned cream. Only two cultures of anaerobic sporeformers were isolated from sound tins. Some evidence was produced that *Bacillus licheniformis* may produce a slight "swell" in canned dairy products. Defects in the sweetened condensed milk samples were due to yeasts when the defect was a "swell." "Buttons" were due to various molds, while progressive thickening was due to various causes.

18. Nichols. 1939. J. Dairy Res. 10, 231-249.

Microscopical examination of 154 cans of four leading brands of evaporated milk purchased on the open market by Deming and Davis¹⁹ showed only an occasional organism in eight cans. In only one case was the number of organisms considerable. Cultural studies were essentially negative except for one can from which was isolated an anaerobe growing at 55°C. (131°F.). The authors conclude that evaporated milk as purchased on the open market is not only free from pathogenic bacteria but may be considered practically sterile. Bacteriologically, this product is regarded as a safe food for infant feeding. Recent investigations have revealed that these products are better bacteriologically today than they were a few years ago. This is due to greater attention to plant sanitation and to better methods of processing.

SPOILAGE OF CANNED CONCENTRATED MILKS

Several different types of spoilage have been encountered in canned milks. The bacteriology of some of them has not been thoroughly worked out. In others, the causal organism was isolated and studied at considerable length. A few of the common types of spoilage will now be discussed.

Formation of "Buttons" in Sweetened Condensed Milk. These are hard, reddish-brown lumps of curd. Rogers, Dahlberg, and Evans²⁰ found that they were due to the growth of *Aspergillus repens* and perhaps other molds on the surface of the milk, after the can had been sealed. On account of the lack of oxygen, the growth of the mold was quite restricted, and it died out in about two weeks. The mold hyphae then broke up and on old cans of milk there were no appearances, whatever, of mold growth. The button is probably formed from the casein by enzymes. Rogers recommended sealing the cans under a vacuum of at least 20 inches, since the mold cannot develop in such concentrations of oxygen. Knudsen²¹ reported "button" formation in condensed milk by *Aspergillus glaucus* and *Catenularia fuliginea*. Savage and Hunwicke, whose report has been rather fully reviewed, did not make routine observations for molds in canned milk. While they were observed a few times, these men believed a greater incidence would have been noted if special attention had been given them. Dixon and Sugden²² observed molds as the cause of "buttons" in two samples which were found to be abnormally thick and to contain a number of reddish, button-like masses. The changes in the milk were evidently caused by the growth of molds induced by storage at too high a temperature. Both samples contained invert sugar, probably produced as a result of the activity of molds. Harris²³ isolated *Monilia nigra* from cans of condensed milk which showed button formation. They were found mainly at the ends of the can. Harris²³ isolated the organism using a medium of dextrose, lactic acid, and yeast water. *Monilia nigra* is a yeast-like organism producing filaments readily, developing a black pigment within 24 hours after the colony is large enough for microscope examination, and not forming ascospores. Its cultural and other characters are described in detail. Inoculations into tins of condensed milk with closure of the cans gave rise to colonies in only one out of six cans.

Buttons are a cause of much trouble in condensed milk. They are caused by molds which are widely disseminated in nature. This makes it possible for them to reach the condensed milk easily, for they may be in the cans when they are filled or in the sugar. The latter may be an important factor if it is not kept scrupulously clean and free from dirt.

Putrefaction of Canned Concentrated Milk. This type of spoilage is no different from that induced in practically all nitrogenous materials. The proteins are hydrolyzed by certain bacteria which survive the process and later attack the milk. Anaerobic sporeforming bacteria, such as *Clostridium putrificum* or members of the *Proteus* group, may be the causal organisms. The changes induced are very much like those of true putrefaction. A few cases have been observed in the author's laboratory. Savage and Hunwicke stated that anaerobic sporeforming bacteria were not important in spoilage of canned milk.

Bitterness in Canned Concentrated Milk. This type of spoilage in canned milk was studied by Hammer.²⁴ A condensory which lost a portion of its pack over a period of time eventually coped with the trouble by increasing the process. Bacteriological examination showed the presence of a sporeforming, facultative organism to which the name *Bacillus amarus* was given. One is impressed by the possibility that this organism is really a member of the *Subtilis-Mesentericus* group. Spitzer and Epple²⁵ found an organism much like *Lactobacillus panis* as the cause of bitterness in evaporated milk. The organism was killed in between eight and 10 minutes at 121.5°C. (250°F.). The organism decomposed proteins to peptones and amino acids. The bitter taste was probably due to these compounds. Savage and Hunwicke examined three old cans of milk from a lot said to be bitter. They were sterile, however.

Gaseous Fermentation of Canned Concentrated Milks. Various lactose-fermenting organisms may cause this spoilage in canned milks. Pethybridge²⁶ investigated the occasional occurrence of spoiled cans of condensed milk in the product of one factory and found the cause to be yeasts. They were not introduced into the milk with the cane sugar used nor were they inhibited in their activity by increasing concentration of the cane sugar. The source of the yeasts was apparently the original milk supply. As the destruction of the yeasts by heat during the manufacture of condensed milk was not practicable, more careful attention was paid to the condition of the milk supply and a considerable improvement followed the rejection of dirty milk. Cassedebat²⁷ could isolate no viable organisms from swelled cans. He believed therefore, as did Dodge²⁸ that spoilage was not due to bacteria. The possibility of auto-sterilization of canned foods was not appreciated then, as it is today. Hammer²⁹ found a budding fungus in cans of hard swelled canned milk to which the name *Torula lactis-condensi* was given. One important contribution in this work of Hammer is that yeasts may cause this type of spoilage. Statements appear in many texts that yeasts rarely ferment lactose. The fermentation of this disaccharide would seem to be common if one took time to study the literature. In a later publication Hammer²⁴ announced two more varieties of yeasts, under the names of *Torula cremoris* and *Torula sphaerica*, which cause the foamy fermentation of lactose. While these yeasts caused no trouble in canned milks, they might, perhaps, do so. Other investigators have also found yeasts to cause spoilage. Savage and Hunwicke⁵ believed yeasts to be common causes of spoilage. The work of Hammer quoted above, was confirmed by Knudsen,²¹ who reported two types of yeasts from swelled cans of sweetened condensed milk. Both yeasts fermented glucose, fructose, and sucrose but not galactose, maltose, or lactose. Ascospores were not formed. No changes were induced in milk, but the addition of a fermentable substance was followed by an active fermentation and coagulation. It was killed by a few minutes' exposure at 55°C. (131°F.). Dutch sweetened condensed milk contained another species. Yeasts were found to be important in condensed milk but of practically no importance in evaporated milk.

Bacteria able to ferment lactose may also be responsible for gaseous fermentation of condensed milks. Rogers and Clemmer³⁰ found *Aerobacter aerogenes* types of organism growing in condensed milk, containing from 40 to 45 per cent of cane sugar. Since

it would not grow in milk containing 40 per cent of cane sugar in true solution, they concluded that there was a crystallization of sugar in the can of milk. They believed that infection occurred between the pan and filling machine. Jandin³¹ isolated a "Bacillus A" which rapidly inverted the sucrose in milk, and caused a vigorous gas formation. Another organism like this, except that it formed acid and coagulated the milk was also isolated. These gas-producing bacteria probably originate in the raw milk. They have been studied by many different investigators because they are, in general, quite undesirable bacteria in milk products. In fresh milk they are killed readily by temperatures of 58.5-63.5°C. (137-146°F.) in 10 minutes (Harrison³²). In condensed milk, however, the situation is quite different. Crystallization of sugar in condensed milk was offered as a reason for the growth of gas-forming bacteria by Rogers and Clemmer.³⁰ They isolated an organism which formed sufficient gas to burst the cans. It was able to endure from 40 to 45 per cent of sugar.

A gas-forming streptococcus to which the name *Streptococcus distendens* was given, was isolated by Hammer³³ from swelled cans of condensed milk. Small quantities of gas were produced along with considerable quantities of volatile acids from some of the constituents in the milk.

Nichols¹⁸ reported that members of the *Escherichia* group were the most common causes of gaseous spoilage.

Coagulation of Canned Concentrated Milk. This is a common type of spoilage, and has caused much concern among those who pack evaporated milk. It is due to a number of causes. Milk with too high an acidity in the beginning may be the cause of it. The presence of certain types of microorganisms may also be the cause. In support of this there are several publications. The contents of a can which has undergone this spoilage, when emptied into a dish, will stand up and retain the shape of the can, especially if it has not been shaken. The milk may have an "off" flavor, but may not be sour. Some cans have a fruity odor and a slightly bitter taste. Considerable bacteriological work has been done on the spoilage.

Grieg-Smith³⁴ isolated an organism which was distinguishable from *Staphylococcus pyogenes albus* only by its nonpathogenicity for mice. Activity of the organism was increased by calcium carbonate. Thayer¹⁷ noticed spoilage of condensed milk 12 to 14 hours after sterilization which was evidenced by a "chug" in the cans upon shaking. Thayer isolated an organism which was believed to be *Bacillus subtilis*. He suggested that the trouble be corrected by raising the temperature and time of processing. Similar organisms were reported by Kelly.³⁵ Three types of bacteria were isolated which reproduced the spoilage when inoculated into sound cans. The bacteria were identified as *Bacillus cereus*, *Bacillus simplex*, and *Bacillus megatherium*. One of the most detailed reports in the literature is by Hammer³⁶ who isolated, from coagulated canned milk, a bacterium to which he gave the name *Bacillus coagulans*. He was able to reproduce this condition in sterile cans by injections of the new organism. Cordes³⁷ also isolated an organism believed to be identical with *Bacillus coagulans* Hammer. Koch's postulates were fulfilled, indicating that the organism was able to produce the decomposition. The organism was found to resist killing by heat at 80°C. (176°F.) for 10 minutes. Cordes also studied the effect of heating in the autoclave. The cells survived heating for two minutes at 106.1°C. (223°F.), between 100°C. (212°F.) and 106.1°C. (223°F.) for three minutes, and between 89.5°C. (193°F.) and 106.1°C. (223°F.) for 12 minutes. Rice and Downs³⁸ have also explained the thickening of sweetened condensed milk on the basis of bacterial action. The specific organism was a coccus which was isolated from the equipment. Growth was prevented by keeping the sugar content up to a concentra-

tion at which the coccus cannot grow. Downs,³⁹ after a study of various organisms isolated from thickened milk, reduced all of them to one general type, of which two distinct varieties were found. Downs stated that the production of acid alone was not responsible for thickening. He believed that thickening was caused by a rennin-like enzyme formed by certain bacteria. The organisms were not named. They were not heat resistant. An organism identified as *Bacillus cereus* was isolated by Hammer and Hussong⁴⁰ from three cans of milk from one batch in which coagulation trouble had occurred. In evaporated milk, in tubes providing access of air, this organism curdled milk rapidly and produced objectionable odor and flavor, but in cans incubated at 37°C. (96.8°F.) coagulation was slow with no change in odor or flavor unless the holding period was prolonged. Owing to the fact that the organism was isolated from only three cans, Hussong and Hammer did not consider it to be the primary cause of coagulation.

While many of the publications on the subject indicate that coagulation may be due to development of certain bacteria, several others suggest other causes. For instance, Rogers⁴¹ and Sommer and Hart⁴² studied the relation of coagulability to acidity and temperature of processing. Increase in acidity did not always accompany lowered coagulation temperatures. Each milk seemed to have a definite hydrogen-ion concentration at which it was stable.

Another outbreak of coagulated canned milk was described by Sarles and Hammer.⁴³ The strain of *Bacillus coagulans* which was isolated was quite like the original. The coagulated milk had no odor of putrefaction.

Abnormal Flavors in Concentrated Milks. Flavor in any food product is an indefinite characteristic, but one, however, which must be taken into account. The element of flavor is especially important with the dairy products where, through training, the consumer has become accustomed to a certain taste. Unfortunately, there is no standard with which to compare such abnormalities, and they are, consequently, known under a variety of names. Those who are familiar with these flavors are adept in identifying them.

Fishy Flavor. Fishy odors and flavors have been noted in practically all dairy products. Hammer⁴⁴ described an investigation of "fishy" evaporated milk and suggested the name *Escherichia ichthyosmia* (*Bacterium ichthyosmias*). Spores were apparently not formed, since they were not observed in the stained preparations, and no growth was secured after heating for 10 minutes at 80°C. (176°F.). It is not at all improbable that the explanation of fishiness in milk by Sommer and Smith,⁴⁵ that it was due to the formation of trimethylamine from lecithin, might hold for the formation of the fishy flavor in concentrated milks.

Common aerobic sporeforming bacteria, *Bacillus mycoides* and *Bacillus mesentericus*, were said to cause fishy milk by Cecelia.⁴⁶ Hammer's organism was not found in a single instance.

Rancidity of Sweetened Condensed Milk. As used by Rice,⁴⁷ who reported a study of rancidity of sweetened condensed milk, the term refers to a flavor resembling that of butyric acid. Twenty commercial samples of rancid condensed milk were found to have a high acidity, a low bacterial content, and to give the peroxidase reaction. Condensed milk prepared in a vacuum pan became rancid when small amounts of unheated milk were made a part of the batch. Raw milk did the same thing in condensed milk of regular manufacture. The active agent was said to be lipase which is destroyed by heat in the regular manufacture of condensed milk in the factory. When unheated milk

gets into the batch through some error, the enzyme hydrolyzes part of the butterfat to fatty acids to which the evidences of rancidity are due.

Tallowiness of Sweetened Condensed Milk. This flavor, according to Rice⁴⁷ who studied its development, resembles to a considerable degree the flavor of tallowy butter and powdered whole milk. The production of this flavor is probably a chemical phenomenon and not a biological one. Rice stated that it was due to the action of oxygen of the air in the container on the butterfat of the milk, the action being catalyzed by a little copper.

Clostridium botulinum in Condensed Milk. The possibility of growth and toxin-formation by *Clostridium botulinum* in canned milk was investigated by Schoenholz, Esty, and Meyer.⁴⁸ Five cans were inoculated with toxin-free spores and stored either at room or incubator temperatures. The contents of one can was tested after 10 days and proved to be slightly toxic to guinea pigs. The appearance was normal. The contents of three other cans after 122 days were coagulated and gave off a strong odor of butyric acid and were very toxic for guinea pigs. Other inoculations into canned milk caused these investigators to reach the following conclusions: (1) spoilage in canned milk after inoculation with *Clostridium botulinum* may be quite irregular; (2) the number of cells introduced apparently makes little difference; (3) the milk appearing normal may be weakly toxic; (4) introduction of soil increased spoilage, but did not increase toxin-formation. They also stated that evidence was secured indicating that toxin, once formed in milk, might deteriorate in the milk. One outbreak of botulism caused by commercially canned milk was reported by the Botulinus Commission (Geiger, Dickinson, and Meyer⁴⁹). The outbreak was not proven toxicologically or bacteriologically.

Canning of Condensed and Evaporated Milks. Concentrated milks have been canned for many years. They have presented problems which have not been easy to surmount, although great progress has been made. The heat which is applied to the cans in the retort probably destroys nearly all of the bacteria in some cans and all of them in others. The heat also brings the milk to the desired consistency. Processers in the past have been prone to relate consistency with sterility, although there is no relation between these two factors. Bigelow⁵⁰ and his colleagues in the Research Laboratories of the National Canners Association have devoted much study to the question of heat penetration into evaporated milk during processing. The introduction of cookers in which the cans may be agitated during processing has greatly improved the sterility of the product.

Vacuum Packed Milk. This process was described by Willison.⁵¹ It was believed that the removal of air would prevent the development of yeasts and molds and thus reduce one of the greatest causes of spoilage. The milk is drawn from the cooler or holding tank into the vacuumizing tank to undergo a violent agitation under high vacuum. The agitation releases occluded air which is then drawn off by the vacuum. As a result of this

51. Willison. 1924. Canning Age, Oct. 1924.

the body of the milk is reduced to a thinner consistency. The vacuumizing took place just before the milk went to the fillers. The belief that removal of air from the cans would reduce spoilage is in keeping with the opinions of Savage and Hunwicke, who stated that entrance of air favored the development of yeast cells which were quiescent.

BACTERIOLOGICAL EXAMINATION OF CONDENSED AND EVAPORATED MILK

The technic for examining these products is quite like that described for canned foods in Chapter 23.

Bacteriological standards have been proposed at various times for condensed milk. Coutts did not favor them but suggested that special attention be given the conditions under which the milk for condensing was produced as well as the conditions under which it was condensed. Savage and Hunwicke also agreed that the bacterial standards would not be of much assistance. They believed, however, that no condensed milk should contain *Escherichia coli*. The presence of this organism was believed to indicate the presence of nonsporeforming bacteria or that contamination of an undesirable character had reached the milk. They were unable to make suggestions with regard to the presence of streptococci on account of the fact that so many streptococci are of no significance.

The cans should be incubated if they have just been packed or may be opened immediately if they are old. After incubation the same procedures may be followed that are described in Chapter 23.

Examination of Stained Centrifugalized Deposit (Savage and Hunwicke⁵). A little of the milk is taken and centrifugalized with water to get rid of fat and other products. If clotted it is first mixed with water and filtered, and the filtrate centrifugalized. If necessary the deposit is remixed with water and again centrifugalized. A little of the deposit is spread on a coverslip, fixed, and stained in the ordinary way. While this gives an idea of the number of bacteria and yeasts present in the milk it does not, of course, distinguish between the living and the dead.

Savage and Hunwicke's Technic for Examination of Condensed Milk for Bacteria. The following procedures were suggested:

1. Pour a few drops of alcohol over the top of the can and burn off.
2. Open with a can opener sterilized in the same manner, or better still, by boring a small hole with a $\frac{3}{8}$ -inch drill, sterilized by burning alcohol.
3. Remove a considerable quantity of condensed milk with a sterile glass tube (about $\frac{1}{4}$ -inch bore) not contracted at the tip. Add this to a weighed, sterilized, stoppered flask.
4. Add a large drop to surface of glucose agar in a petri dish and distribute over the surface.

The flask should then be weighed to determine the amount of milk which should not be less than five grams. A simple calculation will give the amount of sterile water to be added to bring the dilution to one to four. For example, if five grams is the amount of milk, the diluted milk should be 20 ml.

Add two ml. of the diluted milk to the culture tubes of plain broth, glucose yeast water, and glucose litmus broth in the double tube. The glucose agar plate and the yeast water should be incubated at 21°C. (69.8°F.) (or better, 25°C. [77°F.] if available) for yeasts, the other tubes at 37°C. (98.6°F.), the meat broth anaerobically for anaerobes, the glucose litmus for aerobic gas-formers, aerobic sporeformers, and bacilli.

Part of the diluted milk may be centrifugalized and stained directly.

DEHYDRATED MILK

This product has much less water than the other concentrated milk products and, therefore, has somewhat different characteristics. Under certain conditions milk powder has distinct advantages. No question need exist as to its sanitary qualities, although Prickett⁵² said that factors are involved in controlling the sanitary quality of dried milk which are additional to those used in ordinary milk control. Since dried milk is frequently made from surplus milk, the sanitary quality of the fluid milk from which it is made may be poor. Experts with this product have stated that the plate count of dry milk may not indicate the quality of raw milk from which it is made. Prickett recommended the microscope method of analysis using a 1 to 10 dilution of the milk powder.

Leary⁵³ stated that "the fact that milk is a fluid, and further, that it is a good culture medium, is responsible for its transmission of disease; and the removal of water from milk makes it a poor culture medium and largely does away with its perishable qualities." While drying greatly reduces the bacterial content, dried milk is not sterile. Two processes are used for dehydrating milk. Leary described them as follows: In the roller process, the milk adheres to the surface of the hot rolls heated by steam to between 110 and 140°C. (230 and 284°F.); as the roll revolves the milk is scraped off in the form of a moist powder, the whole procedure requiring not over a few seconds. In the spray process, the milk is atomized under great pressure into a chamber where it encounters currents of warm air. The warm air removes the water from the milk. In order to prevent caking and cause more rapid solution in water, the milk is usually concentrated before atomizing.

Considerable study has been given to the bacteriology of dehydrated milk. Some of these reports will be reviewed even though the data and conclusions are contradictory. In the examination of six different kinds of dried-milk preparations, Prachfeld⁵⁴ found from 4,000 to 69,000 bacteria per gram. The nature of the organisms indicated that they entered the milk after drying. Hoffmann⁵⁵ obtained results from inoculation experiments with guinea pigs, showing that *Mycobacterium tuberculosis* (bovis) was destroyed in the manufacture of milk powder by the Just-Hatmaker process. Kossowicz⁵⁶ found that drying reduced the bacterial content to some extent. *Bacillus sinapivagus*, *Serratia marcescens*, and *Pseudomonas fluorescens*, however, were not destroyed. Dried milks may become reinfected if not kept in closed vessels. Ten per cent solutions of the powder showed aerobic bacterial growth at 22°C. (71.6°F.) ranging in numbers from 100 to 757,000 per ml., and at 37°C. (98.6°F.) from 1,000 to 892,000 per ml. The results for the most part, however, ranged under 10,000 per ml. in each case. The presence of streptococci, *Salmonella enteritidis*, and *Escherichia coli* was recorded in many of the samples. There

was no evidence of tuberculosis in guinea pigs inoculated from these samples. According to Supplee and Ashbaugh,⁵⁷ a bacterial content of over 1,000 per gram in milk powder made by the Just process indicates recontamination, since the bacteria are usually fewer in this product than in milk dehydrated by the spray process. The number of bacteria in the milk before drying does not influence the number in the dried milk. Bacteria were said to die off during storage, approaching constancy after two to four months. Even large numbers of bacteria in the powder were said to have little influence on keeping quality if the moisture content is kept below that usually allowed in commercial powders. Fuller and France⁵⁸ reported negative results when milk dried by the roller and spray processes were examined for *Mycobacterium tuberculosis*.

Very interesting are the statements of Kossowicz,⁵⁹ that only sanitary milk should be used in making powdered milk. He stated that even non-sporebearing bacteria survived drying by the Hatmaker "drying roller" process. The spray process was stated to yield a product with bacteria; even more were found in the milk concentrated in a vacuum and dried slowly at low temperatures. The high bacterial content of a dehydrated milk is also borne out by Delepine's⁶⁰ work in England. In the Journal of State Medicine⁶¹ it was stated that in milk powder made by the Hatmaker process the numbers of bacteria were reduced from 70 to 120 million per ml. to 70 to 120 per ml. Experiments also indicated that *Mycobacterium tuberculosis* was destroyed by this process. The accessory substances seem to be reduced during dehydration.

Reduction in the total number of bacteria, according to Delepine, was almost entirely due to the death of Streptococci, Staphylococci, Sarcinae, bacilli of the *Escherichia coli* type, Streptothrices, yeasts, etc. At none of the stages of preparation was the milk ever found completely sterile. Some living tubercle bacilli of bovine origin were found to have survived treatment of drying milk over heated, revolving cylinders, while the drying of milk in a current of hot air had even less effect on tubercle bacilli. These bacilli were capable of producing tuberculosis in guinea pigs, but the course of the disease was much slower than when the same amount of untreated tuberculous milk was used. There is room for more work on the effect of different methods of drying on *Mycobacterium tuberculosis*. That the initial number of bacteria in the milk, before drying, has much to do with the number in the dry milk, is suggested by data reported by Hunwicke and Jephcott.⁶² Desiccation of milk by the roller process which had been inoculated with *Escherichia coli*, *Aerobacter cloacae*, *Sarcina lutea*, *Staphylococcus albus*, a long chain streptococcus, and an encapsulated organism producing a red pigment, practically sterilized it. The only milk containing bacteria after drying and reconstituting was one

which originally had 2,000,000,000 bacteria per ml. and, after drying, four per ml. Milk inoculated with *Bacillus subtilis* and *Bacillus mycoides* showed a greater number of surviving cells. Similar results were secured by Dick and Dick.⁶³ They stated that many of these bacteria would appear in the food of infants prepared from milk powder, if the milk was not boiled. Schrader, Ewing, Korff, and Conn⁶⁴ examined 100 samples of milk powder from widely different sources. They were examined for total count, *Escherichia coli* count, Breed count, and for *Mycobacterium tuberculosis* by animal inoculation. All of the samples were negative for *Mycobacterium tuberculosis*. The counts by the standard plate and the Breed method were variable. These authors believed that there was still opportunity for improvement in handling milk powder. Macy⁶⁵ used drum and spray-dried milk powders, in the fresh condition, and after storage for up to six years. Original counts per gram on spray samples varied from 4,400 to five and one-half million, averaging over 50,000; on drum samples 40 to 79,000, averaging below 500. There was a decrease of over 90 per cent on one year's storage, and a greater decrease with increase of storage temperature up to 37°C. (98.6°F.) with spray process powders. He also said that the types of bacteria present in the dried milk vary with the drying process.

According to Supplee and Bixby,⁶⁶ dry milk, made by the Just roller process, rarely has a bacterial content of over 1,000 per gram. Many undesirable bacteria were destroyed by this process. On account of the conclusions reached by Dick and Dick⁶³ that undesirable streptococci might not be killed, Supplee and Bixby dried milk which had been artificially inoculated with hemolytic and green-producing streptococci. All were destroyed.

Four hundred seasonal samples of spray-dried milk powder examined by Nichols⁶⁷ from factories in England and Scotland showed wide variations in bacterial content and methylene blue reduction times. Plate counts varied from 1,400 to 149,000,000 per gram and reduction times from three to 14 hours. Variations in quality of milk powder from the same plant was attributed to processing methods and presence of heat-resistant microorganisms, such as thermoduric and thermophilic bacteria. After aging at room temperature for 12 months, the mean reduction in bacterial content was 95 per cent. Heat-resistant streptococci predominated in the milk. Crossley⁶⁸ also found large numbers of microorganisms. He thought that the plate count could be used as an index of the quality of raw milk from which the milk powder was made. Thermophilic bacteria were reported to be present in skim-milk powder by Sorensen.⁶⁹

MICROBIOLOGICAL EXAMINATION OF MILK POWDER

Less attention has been given to methods for the bacteriological examination of milk powder than has been given to methods for examination of

other products. After the powder has been reconstituted, the regular methods for examination of fluid milk may be used. Miller and Prickett⁷⁰ and Prickett⁷¹ believed that the sanitary condition of milk powder could be ascertained by determining the "standard plate count" per gram, a similar count with plates incubated at 55°C. (131°F.), a microscope count, a mold count, and a sediment test. Prickett⁷¹ placed considerable confidence in the microscope count because it enumerated both living and dead bacteria and thus gave more information concerning the previous history of the powdered milk. Although the standard plate count was said to be beset with several difficulties which were discussed by Prickett, it was considered to be an important step in bacteriological control of this product.

Comprehensive observations were made by Curtis and Hileman⁷² on media and incubation temperatures which might be used for making bacterial counts of dry skim milk. In this work 254 samples of spray-process, dry skim milk were plated on standard agar and tryptone-dextrose skim milk agar recommended by Bowers and Hucker. The plates were incubated at 37°C. (98.6°F.) and at 32°C. (89.6°F.) for 48 hours. The tryptone agar and lower incubation temperatures both resulted in higher counts. The medium was more important in a greater increase in count than was lowering the incubation temperature. This was said to be contrary to results obtained on other dairy products for usually lowering of the incubation temperature has resulted in the greater increase. Curtis and Hileman explained this by the fact that the methods of making dry skim milk might result in a richer flora of heat-resistant bacteria, growth of which would be favored by the tryptone agar. Other dairy products are stored at low temperatures which would probably result in a flora which would grow better at lower temperatures.

Bacterial Standards for Milk Powder. Quality of raw milk from which milk powder is made or of the final product itself is probably not indicated by the number of bacteria in it as determined by the plate count. The method of manufacture determined to a great extent the number of microorganisms that may survive. For "Extra Grade" dry skim milk the Dry Milk Institute suggests no more than 15,000 bacteria per ml. of reconstituted milk; for "Standard Grade" no more than 50,000 per ml. whether these milks are made by the spray process, vacuum drum process, or atmospheric roller process.

American Dairy Science Association⁷³ Procedures for Examination of Milk Powders. These procedures resulted from actions of the committee on bacteriological methods of analysis and have been used as the basis for statements of procedure by later workers.

Samples. It is important that all apparatus be clean and sterile and that the sample be taken as speedily as possible. Samples should be taken at points beneath the surface in order to avoid those which may have been unduly contaminated. If the lot to be sampled is a large one, it is better to remove portions from different points throughout the mass. Such portions should be combined in a larger container and thoroughly mixed. Sterile spoons or spatulas may be used.

70. Miller and Prickett. 1933. Milk Plant Mo. 22, 24-29.

71. Prickett. 1939. J. Milk Tech. 2, 133-137.

72. Curtis and Hileman. 1937. Food Research 2, 73-80.

73. Down (Chairman). 1932. J. Dairy Sci. 15, 383-389.

Standard Agar Plate. The procedures recommended by the American Public Health Association for determining the plate count of fluid milk are used. For the one-to-ten dilution, 10 grams of milk powder are added to 99 grams of sterile water in a dilution bottle; or, if desired, five grams of the powder may be added to 45 grams of water. Dilutions for plating should be made so that plates with not less than 30 or more than 300 colonies per plate are available for counting. If lactic acid, milk-powder preparations are being analyzed, N/10 lithium hydroxide should be used as diluent to facilitate dissolving the sample. The plates should be incubated for two days at 37°C.(98.6°F.), as recommended in the standard procedures of milk analysis. Other temperatures may be used in special work, such as incubations at 55°C.(131°F.), to determine the number of thermophilic bacteria which are present. In counting, great care should be exercised to distinguish between colonies and débris on the plates. Doubtful objects should be scrutinized with a lens to determine whether they might be bacterial colonies.

The Microscope Count. This may be done either by the Frost method or by the Prescott-Breed method. If the Frost method is used, the little plates should be incubated for from 12 to 16 hours at 37°C.(98.6°F.). The committee did not believe that the latter was an adequate method for determining the bacterial content of milk powder. It was said to be of supplementary value in conjunction with plating procedures.

Examination for Hemolytic Streptococci. These organisms should be determined by use of blood agar plates prepared by adding .5 per cent of sodium chloride and from two to five per cent of defibrinated blood to standard nutrient agar medium. These plates should be incubated for two days at 37°C. Suspicious colonies should be examined by the Gram stain to determine presence of streptococci.

Examination for Thermophilic Bacteria. For routine work plates should be prepared with standard nutrient agar medium. They should be incubated for 48 hours at 55°C.(131°F.). In order to prevent drying, at least 15 ml. of medium should be used in each plate.

Examination for Yeasts and Molds. When it is desired to examine milk powder for yeasts and molds, procedures devised for butter may be used.

Reporting of Results. These should ordinarily be per gram of dry powder. If desired they may be transformed to the fluid basis by dividing by the factor used in reconstitution. This is usually eight parts of water to one part of powder.

Thompson, Slemmons, and Fleming's⁷⁴ Method for Bacteriological Examination of Dry Skim Milk. The authors of this method constituted the Standards Committee of the American Dry Milk Institute. They proposed the following method:

A. Completely disperse 10 grams of a well-mixed powder in 100 ml. of sterile, distilled water. It is suggested that this be done by weighing 10 grams directly into a six-ounce sterile bottle containing 100 ml. of sterile water and furnished with a sterile rubber stopper. It is important that the mixture be thoroughly shaken so as to make sure that the powder is completely dispersed.

B. After reconstitution as in A, follow the procedure as outlined for the microscope colony count (plate method) as published in the Standard Methods of Milk Analysis of the American Public Health Association. It is important to note that the final count is to be expressed as the plate count per milliliter of the reconstituted solution. The American Dry Milk Institute established two grades of dry milk: "extra grade" and "standard grade." The former should not contain over 30,000 bacteria per ml. and the latter not over 100,000 bacteria per ml., whether "spray dried," "vacuum drum dried," or "roller dried." This technic was adopted as official by the American Dry Milk Institute.

American Dry Milk Institute⁷⁵ Procedures for Bacteriological Examination of Milk Powder. Completely disperse 10 grams of the sample in 100 ml. of sterile distilled water. This may be done by weighing two grams directly into a six-ounce bottle containing 100 ml. of sterile water and furnished with a rubber stopper. Shake the bottle vigorously to break lumps and assure distribution of bacteria. After this the standard procedure for examination of milk as given in *Standard Methods for Examination of Dairy Prod-*

74. Thompson, Slemmons, and Fleming. 1930. J. Dairy Sci. 13, 319-335.

75. The Grading of Dry Milk Solids. Amer. Dry Milk Inst., 221 No. LaSalle St., Chicago, Ill.

acts should be followed. Further dilutions of the reconstituted milk should be made so that plates may be counted which have not less than 30 or more than 300 colonies per plate. The results are to be expressed as the number of bacteria per ml, of reconstituted milk.

Microbiology of Infant Foods. An important baby food is milk powder, the microbiology of which is discussed here. Dick and Dick⁶³ showed that the use of milk powder for the preparation of feedings for infants permitted many bacteria to be ingested. A feeding prepared at one institution from a sample of protein milk contained 22,000 bacteria per milliliter, of which 11,000 were green-producing streptococci. A similar feeding prepared at another institution from another sample of protein milk contained 9,000 bacteria in one ml. with 7,000 green-producing streptococci. Results of an extensive investigation on infant foods were published by Hucker and Hucker.⁷⁶ Samples of prepared infant foods secured from the manufacturers and on the open market contained living bacteria varying from 10 to over 600,000 per gram of dried material. The principal organisms were spore-bearing types, many of which were thermophiles. Hucker and Hucker stated that no hemolytic streptococci should be permitted nor should the total count be more than 10,000 per gram. Careful attention to plant sanitation and other factors permitted manufacture of products which were consistently below this standard. Giblin and von Pourtales⁷⁷ examined 200 samples of dried-milk preparations used in infant feeding. The total count varied from 1,000 to 10,000 per gram. No pathogenic streptococci nor tubercle bacilli were observed, indicating that the standards suggested by Hucker and Hucker were being met.

Of 20 brands of powdered infant foods studied by Mattoon,⁷⁸ average total colony counts made on standard agar ranged from 37 to 98,000 per gram after 48 hours' incubation at 37°C.(98.6°F.). The majority of organisms found were sporeformers, ranging from seven to 29,900 per gram, though micrococci, streptococci, nonsporeforming rods and a few sarcinae, yeast, and molds were found. Gelatin liquefiers varied from 0 to 34,000 and the number of chromogens from 0 to 8,900 per gram. No coliform colonies were noted. Average total counts of hemolyzing colonies were from 0 to 19,800 per gram, though individual counts as high as 160,000 were obtained: Viridans and beta hemolytic streptococci were found in five different products, and their presence was questioned in two others. In one product these organisms numbered as high as 160,000 per gram. Cultures obtained from this sample were not pathogenic for guinea pigs.

CHAPTER 12

FERMENTED MILKS

Milk has been fermented for ages by nomadic people. Fermented milks were first used for their food values. Gradually, they have been used for whatever therapeutic value they might possess. Interest in this latter use, and indeed in the entire subject of intestinal bacteriology, was greatly aroused by Metschnikoff's book, *The Prolongation of Life*, in which it was stated that senility was related to autointoxication in the digestive system. He believed that the evil consequences from constipation are due, mainly, to retention of fecal matter and undigested food residues in the intestines. Toxic substances and even putrefactive bacteria were believed to be absorbed into the blood. He observed the numerous instances of old age among people of the Balkans, and resorted to the unique explanation for which he is so well known today. A discussion of this subject with the literature has been prepared by Rogers.¹ Since Metschnikoff published his interesting conclusions, many others have studied the subject. While, in general, the beneficial results of ingestion of fermented milks have been confirmed, not all of Metschnikoff's conclusions have been accepted. Metschnikoff's reputation undoubtedly suffers from unwarranted interpretations which have been made of some of his statements.

Considerable confusion exists today in this field. This may be explained, perhaps, by the fact that there is no certainty that some investigators really had the organism which they said they were using. It is probable that Metschnikoff may have had one organism at one time, another at another time, or perhaps mixtures of types.

Cohendy,² one of the first to show that feeding of milk containing *Lactobacillus bulgaricus* was beneficial, reported that the organism could be implanted, in this manner, in the intestines; a conclusion which was not confirmed by investigators. He further reported, however, that the diet had much to do with the sojourn of the organism in the intestines. Cohendy and Belonovsky³ believed that *Lactobacillus bulgaricus* remained in the intestines for some time. This has since been disputed by Rahe⁴ and others.

It was believed that if intestinal putrefaction could be prevented, senility and premature death could be inhibited. Metschnikoff, therefore, advised the drinking of large amounts of sour milk which would contain both lactic acid and the organisms producing it. Putrefactive bacteria would then be checked because it is well known that they cannot thrive in an acid environment.

Rettger⁵ and his colleagues at Yale University, who have done much work on this subject, showed in 1915 that sweet as well as sour milk

functioned alike in altering the intestinal flora. Furthermore, sour milk containing *Lactobacillus bulgaricus* was no more beneficial than milk with the ordinary lactic acid bacilli. Working with white rats, they found that lactose would give the same results. From this, Rettger⁶ reasoned that it was the lactose in the milk that exerted the effects which were attributed to sour or sweet milk. This lactose created the optimum conditions for the proliferation of the aciduric group of bacteria. Cheplin and Rettger⁷ later reported that lactose was quite as beneficial as sour milk in the diet. They also claimed that Metschnikoff and his collaborators probably worked with *Lactobacillus acidophilus*, believing that they had *Lactobacillus bulgaricus*. Cheplin and Rettger found that a milk diet would completely suppress the ordinary flora of the intestines and establish a flora made up of *Lactobacillus acidophilus*. The work was, in general, confirmed by Torrey,⁸ working with dogs. Not all sugars were able to alter the flora to the same degree. Sucrose, maltose, and glucose gave far less striking changes in flora to the aciduric type than did lactose and dextrin. Glucose and maltose, even in large amounts, exercised no transforming effect on the types of bacteria which were present in the intestinal tract. Torrey did report the interesting observation that there was a difference in flora when boiled milk or unboiled milk was used. With unboiled milk, *Escherichia coli* and streptococci predominated while with boiled milk streptococci and *Lactobacillus acidophilus* outnumbered the other organisms. With regard to the proteins causing a putrefactive flora, it was found that mammalian tissue caused the most pronounced change to an obligate putrefactive flora.

LACTIC ACID BACTERIA AND INTESTINAL THERAPY

The lactic acid bacteria are those which produce appreciable amounts of lactic acid in the fermentation of sugars. Rettger⁹ distinguished the following three main groups:

1. *Escherichia coli* and *Aerobacter aerogenes*.
2. *Streptococcus lactis*, Lister (*Streptococcus lacticus*), Kruse.
3. *Lactobacillus caucasicus*, Beijerinck (*Bacterium caucasicum*), Kern.

The members of these three groups are materially different from one another. The coli-aerogenes types grow well on laboratory media, producing many different products. These organisms are prevalent in some milk but are not as important as the species in the other groups.

In contrast with the members of the coli-aerogenes group, *Streptococcus lactis*, Lister (*Bacterium lactis acidii*, Leichmann, *Streptococcus lacticus*, Kruse, *Micrococcus lacticus*, Migula) is commonly present in milk. It brings about changes which are quite well understood and which, under some conditions, are quite desirable. It functions, for instance, in producing desirable flavor and aroma in cream ripening.

The third group, the *Lactobacillus caucasicus*, Beijerinck group, is the one of main interest at this time. This organism has been used to designate

9. Rettger. 1923. Proc. World's Dairy Cong. 2, 1136-1144.

the group because Massol, Moro, and Tissier had not named their organisms when Beijerinck named his. In this group may be placed the well-known organisms:

Lactobacillus caucasicus (Kern), Beijerinck (*Bacillus caucasicus*, Kern).

Lactobacillus bulgaricus (Grigoroff), Holland (*Bacillus bulgaricus*, Grigoroff).

Lactobacillus acidophilus (Moro), Holland (*Bacillus acidophilus*, Moro).

Lactobacillus bifidus (Tissier), Castellani and Shalmers (*Bacillus bifidus*, Tissier).

Rettger has stated that these organisms cannot be easily separated by common laboratory tests. All three types (*Lactobacillus bulgaricus*, *Lactobacillus acidophilus*, and *Lactobacillus bifidus*) are strongly Gram-positive, are rod-shaped, often grow in long filaments, etc. All three types are distinctly pleomorphic. The growth on ordinary culture media is delicate. They differ, as stated below, in their normal habitat. It is quite possible that some of the confusion in the literature on these intestinal forms may be explained on the basis that the investigators were not certain of the identity of the organisms which they were using. Cruickshank and Berry¹⁰ found a wide range of morphologic appearance of aciduric bacteria in feces from adults and infants. They believed that the name *Lactobacillus acidophilus* covered a considerable group of organisms and that numerous strains might exist in one sample of stool. Considerable confusion may arise in the use of such terms as acidophile. Close distinctions are frequently not made, and specific terms are made to cover much more ground than they should. Schlirf,¹¹ for instance, stated that some forms should be called acid tolerant rather than acidophilic. Perhaps it is better to use the actual names of species and thus avoid the use of collective terms.

***Lactobacillus bulgaricus* (*Bacterium bulgaricum*).** This organism was isolated from sour milks, especially those milks common in the countries of southern Europe. Rettger⁹ stated that the organism was isolated in Massol's laboratory by Grigoroff¹² at the behest of Metschnikoff. Bergey *et al.*¹³ gave Grigoroff credit for isolating the organism. Metschnikoff believed that the well-being of the Bulgarians and other Balkan peoples was due to the almost constant use of sour milk. The beneficial action of sour milk was ascribed to one organism *Lactobacillus bulgaricus*. Metschnikoff believed that when this organism was taken by the mouth it replaced other types which were far less desirable, such as those which brought about intestinal putrefaction. It is, without doubt, a very desirable organism but one which has been confused with other closely related species. It has probably received credit for results actually due to *Lactobacillus acidophilus*.

Lactobacillus bulgaricus has a voluminous literature of its own, all of which cannot be reviewed here. An extensive comparative study of *Lactobacillus bulgaricus* and *Lactobacillus acidophilus* was carried out by Kulp and Rettger.¹⁴ They made no attempt to include various lactobacilli other than varying strains designated under the above names. The first problem

was to find a medium on which the organisms could be grown. Their efforts to solve the question resulted in a casein-digest medium. For securing acidophilus strains, they used the discovery of Rettger and his associates that the feeding of lactose or dextrin would cause a transformation in the intestinal flora to the aciduric types, and since *Lactobacillus acidophilus* is an intestinal form, it would thus appear. *Lactobacillus bulgaricus* strains were secured from the Bureau of Animal Industry and several other sources. They found close resemblance between the members of the *Lactobacillus acidophilus* and *Lactobacillus bulgaricus* types. The strains used were fairly representative of the organisms found in fermented milks and in the intestines of man and animals, characterized by the production, in part or altogether, of sea-urchin-like colonies in agar and in gelatin media. The *Lactobacillus bulgaricus* type appeared to be more constant than the *Lactobacillus acidophilus* type in this respect. The morphology of the two groups was quite similar.

The one outstanding difference between the two types was their habitat. In no case in the course of this investigation had an organism been isolated from feces which had the characteristics of a typical *Lactobacillus bulgaricus* strain. Herter and Kendall,¹⁵ Rahe,⁴ and Rettger and Cheplin¹⁶ proved that *Lactobacillus bulgaricus* cannot be implanted in the intestines of man or animals. In the course of an unfinished experiment, they were not able to recover a non-maltose-fermenting *Lactobacillus bulgaricus* from the feces of white rats after two weeks' feeding of large milk cultures of *Lactobacillus bulgaricus* plus lactose. On the other hand, the ingestion of milk or broth cultures of *Lactobacillus acidophilus*, or the use of a high lactose or dextrin diet alone (Rettger and Cheplin), brought about a transformation of the intestinal flora to such an extent that *Lactobacillus acidophilus* became the predominating organism. Therefore, they concluded that the normal habitat of *Lactobacillus acidophilus* is the intestine of man and animals.

Origin of *Lactobacillus bulgaricus* can only be a matter of conjecture. Was it always a saprophyte living in milk, possibly coming from soil? Or, may it not be a degenerate form of *Lactobacillus acidophilus*, requiring milk as food because of long acclimatization to this medium? Rettger and Cheplin accept the latter explanation for reasons which cannot be given in detail here. They center around the nutrient properties of milk.

Several of those who have studied these organisms have suggested that many of the older names be dropped. Heinemann and Hefferan¹⁷ and Makrinoff¹⁸ would place them all in the *Lactobacillus bulgaricus* group. White and Avery¹⁹ believed them to be identical with *Lactobacillus caucasicus*. The great difficulty of identifying members of the lactobacillus genus was emphasized again by Hunt and Rettger.²⁰ They stated that, at

20. Hunt and Rettger. 1930. J. Bact. 20, 61-83.

times, there are greater differences in fermentation reactions of two given strains of the same organism than are seen between two individuals of different species. Hunt and Rettger pointed out that the soil and grain strains of lactobacilli do not ferment lactose while *Lactobacillus bulgaricus* and *Lactobacillus acidophilus* do. Sherman and Hodge²¹ regarded it as significant that freshly isolated *Lactobacillus bulgaricus* grew at 60°C. (140°F.) and showed vigorous growth at 55°C. (131°F.), whereas old laboratory cultures had a maximum temperature of about 50°C. (122°F.). *Lactobacillus bulgaricus* rarely grew at 15°C. (59°F.), whereas *Lactobacillus acidophilus* usually did.

Characteristics of *Lactobacillus acidophilus* and *Lactobacillus bulgaricus*. The characteristics of these organisms merge to such an extent that it is difficult to distinguish one from the other. During the past few years several methods have been suggested for separating the two organisms. Kulp and Rettger¹⁴ believed that the action of the organisms on maltose, sucrose, and levulose might be of value. *Lactobacillus bulgaricus* did not ferment levulose; *Lactobacillus acidophilus* did. *Lactobacillus acidophilus* fermented maltose and sucrose. Day and Gibbs,²² however, reported that fermentation of maltose, sucrose, and levulose did not differentiate these organisms. Kulp²³ suggested that tolerance for indol or phenol might be used for differentiating these species. *Lactobacillus bulgaricus* was said to be only slightly tolerant to these compounds, which may explain why it does not live in the intestine. Albus and Holm²⁴ observed that *Lactobacillus bulgaricus* would not grow in a medium the surface tension of which had been reduced to less than 40 dynes, but *Lactobacillus acidophilus* showed good growth in the same medium when the surface tension was depressed to 36 dynes. They then suggested that this was a plausible explanation for failures to implant *Lactobacillus bulgaricus* in the intestines. Kopeloff and Beerman²⁵ confirmed the work of Albus and Holm. They used sodium ricinoleate as a surface tension depressant, with six strains each of *Lactobacillus acidophilus* and *Lactobacillus bulgaricus*. Day and Gibbs, however, were unable to concur in these conclusions. They stated that no instance was found in which inhibition of growth could be attributed to lowered surface tension. Sodium ricinoleate was found to exert a toxic action towards the two microorganisms, but this action could not be used as a means of differentiation.

Possibility of using the kind of lactic acid formed by members of the genus lactobacillus has also been suggested as a means of differentiation. Curran, Rogers, and Whittier²⁶ were able to establish two groups of lactobacilli on the basis of the kind of acid formed, temperature characteristics, colony type, carbohydrate fermentations, and inhibition by phenol and indol. About one-half of the strains used agreed with what is usually

considered to be *Lactobacillus acidophilus*. They showed a high positive correlation in production of inactive lactic acid, formation of R or fuzzy colonies, failure to grow above 46°C. (114.8°F.) or as low as 20°C. (68°F.), fermentation of raffinose, and failure to ferment mannitol. As a rule these cultures formed more carbon dioxide and a larger proportion of volatile acids and grew in higher concentrations of phenol and indol than the strains in the other group. A large percentage of the strains of known intestinal origin were in the *Lactobacillus acidophilus* group. The results reported by these investigators show again what a labile group of organisms we are dealing with. Kopeloff and Kopeloff²⁷ related the types of lactic acid produced to the types of form, R or S, which might be present. The R form of *Lactobacillus acidophilus* produced inactive lactic acid. The R form of *Lactobacillus bulgaricus* produced inactive lactic acid in the first six fractions, while the seventh yielded the dextrorotatory enantiomorph. The latter represented one-sixth of the total zinc salt. The S forms of both *Lactobacillus acidophilus* and *Lactobacillus bulgaricus* produced dextrorotatory lactic acid. It is suggested that some of the inconsistencies reported in the literature might be due to the use of cultures containing mixtures of R, S, or intermediate forms.

A few attempts have been made to determine whether *Lactobacillus bulgaricus* can survive in cultures with other lactic acid bacteria. Vas,²⁸ for instance, cultured *Lactobacillus bulgaricus* with *Streptococcus lactis* and studied the amount of acid formed. The amount of acid necessary to coagulate milk was the same in each case, but when grown together the organisms stimulated each other, producing the necessary degree of acidity for coagulation much sooner. Rogers²⁹ found that when milk was inoculated simultaneously, both would grow, but when a heavier *Streptococcus lactis* inoculation was used or if the organism was allowed to grow for a while before *Lactobacillus bulgaricus* was put in, the latter organism did not thrive immediately, but after a few days it began to develop. The inhibiting factor was removed by heating and by filtering through clay or plaster of Paris filters.

Development of *Lactobacillus bulgaricus* in milk is greatly influenced by other bacteria which may be present. When Rogers²⁹ inoculated sterile milk with equal amounts of *Streptococcus lactis* and *Lactobacillus bulgaricus*, the latter predominated. If the inoculation of *Streptococcus lactis* is two to three times as great as *Lactobacillus bulgaricus* only slight development of the latter occurs. When a mixed culture is held for a few days *Lactobacillus bulgaricus* finally develops. Antagonism of these organisms was further shown by growing a culture of *Lactobacillus bulgaricus* in a collodion sac placed in a culture of *Streptococcus lactis*.

Implantation of *Lactobacillus bulgaricus* in the Intestines. There is no field in microbiology where more unwarranted assumptions have been made than in the exploitation of the uninformed with *Lactobacillus bulgaricus*

27. Kopeloff and Kopeloff. 1937. J. Bact. 33, 331-334.

preparations. Fortunately, the researches of Rettger and his colleagues at Yale University have largely cleared this field. Cheplin and Rettger⁷ failed in every instance to implant *Lactobacillus bulgaricus* in the intestines. They secured these results with both rats and men. This was confirmed by Smith.³⁰ Kopeloff³¹ tried to implant *Lactobacillus bulgaricus* into the intestinal tract of 12 psychotic women, some constipated, the rest not. Over a period of 10 to 15 days, daily doses of *Lactobacillus bulgaricus* milk (?) containing 50,000,000 viable cells per ml. were used. In 10 subjects no *Lactobacillus bulgaricus* cells were isolated from the feces. A negligible number was found in the feces of one patient; these finally disappeared entirely. While no implantation was observed, Kopeloff was reluctant to state that such implantation was impossible, since the number of cells in the milk was considerably lower than the number used in acidophilus milk. Kulp²³ carried out experiments to determine the viability of *Lactobacillus acidophilus* and *Lactobacillus bulgaricus* in the human intestine. Several strains of each species were employed. The organisms were ingested as milk cultures, the subjects taking one to three pints daily during each experiment. Whole, sweet, and *Streptococcus lactis* soured milk were fed previous to these experiments as control diets. The results appear to justify the conclusion, that typical *Lactobacillus acidophilus* is viable in the intestine, while typical *Lactobacillus bulgaricus* is not. Emphasis was placed on the point that isolations of *Lactobacillus acidophilus* should be thoroughly tested upon normal individuals, before these cultures are advocated for therapeutic use. Failure to implant *Lactobacillus bulgaricus* may be due to the fact that this organism cannot tolerate indole and skatole as shown by Kulp, or an unsuitable surface tension of intestinal contents.

Lactobacillus acidophilus. This organism was isolated by Moro in 1900 and was named *Bacillus acidophilus*. Unlike *Lactobacillus bulgaricus*, it is a normal inhabitant of the intestines, and can be made to proliferate there by use of an appropriate diet. The experiments on which this statement is based were carried out mainly in Rettger's laboratory at Yale University with a sufficient number of confirmatory papers from other laboratories to justify acceptance of the conclusions. Frost and Hankinson³² published an annotated bibliography on this organism.

Implantation of *Lactobacillus acidophilus* in the Intestines. The early work by Cheplin and Rettger³³ was done with white rats. They observed that the addition of two grams of lactose daily to the basal ration of bread and meat caused a pronounced transformation. *Lactobacillus acidophilus* replaced practically all other types. One gram brought about only a partial change. Combination of lactose with culture produced good transformation. According to Rettger and Cheplin,³⁴ *Lactobacillus acid-*

ophilus may be implanted in the intestines by oral administration of various preparations, as follows:

1. Ingestion of 300 to 400 grams of lactose or dextrin daily.
2. Daily ingestion of 300 ml. of whey broth culture of *Lactobacillus acidophilus*.
3. Daily ingestion of a combination of 150 grams of lactose and 150 ml. of bacterial culture.
4. Daily ingestion of 500 to 1,000 ml. of acidophilus milk.
5. Daily ingestion of 500 ml. of acidophilus milk and 100 grams of lactose.

They stated that the acidophilus milk, of the methods mentioned above, was the best. The milk method stimulated change in bacterial types within the intestines more quickly and perhaps more effectively than feeding the carbohydrate or the whey broth culture. They reported that in two men 500 ml. of acidophilus milk brought about marked alteration in the flora within two to three days. All of the subjects responded to 1,000 ml. of the milk, and a change in the flora of the intestines was produced more quickly and perhaps more effectively. No success was attained in attempts to implant *Lactobacillus bulgaricus* in the human intestinal tract thus supporting the conclusions of the experiments with rats. The hydrogen-ion concentration of the intestines was not changed and consequently this could not be offered as an explanation of the change in flora. The change in type of predominating organisms could be followed culturally. This work was extended by Rettger and Cheplin to pathological cases. One quart of acidophilus milk a day caused a response in an aggravated case of constipation within a week. The same beneficial results were secured in cases of chronic diarrhea, colitis, sprue, and dermatitis. Cannon³⁵ and Gompertz and Vorhaus³⁶ also reported beneficial results from using culture of *Lactobacillus acidophilus*. Cases of chronic constipation and diarrhea were greatly benefited. In a later paper, Gompertz and Vorhaus reported further improvement after the use of acidophilus milk. This was attributed solely to decreased activity of bacteria of the coliform group. They believed, however, that broth cultures were the best way of giving *Lactobacillus acidophilus*. This was said to be more pleasant for the patient and more accurately controlled by the physician. They called attention to the fact that indiscriminate use of *Lactobacillus acidophilus* in all sorts of ailments would tend to discredit it and send it to the same oblivion that *Lactobacillus bulgaricus* now has. Some believe that this time has already come. Kopeloff and Cheney³⁷ also reported confirmatory observations. Less favorable results, however, were reported by Bassler and Lutz.³⁸ Bass and Jones³⁹ wondered whether acidophilus milk had therapeutic value even though it is possible to change the intestinal flora with it. If it is used, they believed that best results are secured when the milk is taken with meals in order to heavily seed the food with viable bacteria. A glass of the milk with each meal was said to be enough. In from four to 10 days a high degree of transformation took place which was main-

tained as long as the milk was continued. When lactose alone was used, daily ingestion of large amounts resulted in rapid increase of *Lactobacillus acidophilus* in due course of time; if the quantity was sufficient, all other bacteria in the intestinal flora were reduced to a negligible number. In some instances, however, more than 300 grams of lactose per day were required to establish *Lactobacillus acidophilus* as the predominating organism. Unfortunately, such a quantity of these sugars is too large to be continued over long periods of time, hence the practical application of this method must be very limited. The investigations of Bass on the use of cultures of *Lactobacillus acidophilus* for therapeutic purposes, including a large number of experiments on 23 different human subjects, yielded results which practically agreed with those of Rettger and Cheplin.

According to Stark, Gordon, Mauer, Curtis, and Schubert,⁴⁰ ingestion of lactose, sweet milk plus lactose, or acidophilus milk with or without added lactose had no material effect upon the numbers of lactobacilli normally growing in the human intestinal tract. However, the types of lactobacilli in acidophilus milk were found in large numbers in fecal specimens from a majority of subjects ingesting this milk but disappeared in two to six weeks after stopping consumption of acidophilus milk even though continuing to take sweet or sour milk with three per cent added beta lactose. The number of coliform bacteria were not greatly changed until acidophilus milk had been taken for three months or more, when a slight decrease occurred. Streptococci and sporulating anaerobes decreased under acidophilus milk therapy. A definite decrease in indol content of the feces occurred in those subjected to acidophilus milk or to sweet milk plus lactose. Moisture content of the stools was increased during ingestion of acidophilus milk but reverted to its original level in four to six weeks in constipated subjects who ceased consuming the milk. Changes in the average weight of the stools occurred in a similar manner owing in part to consumption of lactose in the milk. Yeasts and sporulating aerobes were unaltered. The pH varied little from the average for human feces, which is 7.3. Good implantation of *Lactobacillus acidophilus* after taking whey cultures, was observed by Brown and Redowitz.⁴¹ They recognized the value of laboratory examination of stool specimens to determine whether implantation had occurred.

Having observed the improvements in health following implantation of *Lactobacillus acidophilus* in the intestines, Kopeloff⁴² attempted to determine whether the essential nature of this phenomenon was physical, chemical, or bacteriological. The following points were established:

1. *Lactobacillus acidophilus* therapy was not a physical phenomenon since patients receiving sterile milk were not relieved of constipation.

2. *Lactobacillus acidophilus* therapy is apparently not a strictly chemical phenomenon since patients receiving *Lactobacillus acidophilus* milk, which has been pasteurized to kill all living forms, were not relieved of constipation.

40. Stark *et al.* 1934. Amer. J. Pub. Health 24, 470-472.

41. Brown and Redowitz. 1935. Penn. Med. J. 39, 73.

42. Kopeloff. 1923. J. Amer. Med. Assoc. 80, 602-604.

3. It is essentially a bacteriological phenomenon since patients were relieved of constipation by the ingestion of milk fermented by *Lactobacillus acidophilus*.

4. Relief from chronic constipation has persisted for six months after *Lactobacillus acidophilus* milk feeding was stopped.

5. Viable *Lactobacillus acidophilus* cells were isolated from the feces six months after the ingestion of the milk.

The work of Torrey and Kahn⁴³ would seem to indicate that *Lactobacillus acidophilus* exerts an antagonistic action on proteolytic bacteria. They placed cubes of coagulated egg albumen in cultures of anaerobic bacteria. Cultures to which *Lactobacillus acidophilus* was added did not attack the coagulated egg white. Even when *Lactobacillus acidophilus* was put into older cultures proteolysis was inhibited. Torrey and Kahn found that different strains of *Lactobacillus acidophilus* possessed different abilities to inhibit proteolysis. The conclusions reported have been quite well confirmed by Cruickshank.⁴⁴

Unfermented Acidophilus Milk. An unfermented acidophilus milk containing a high concentration of viable *Lactobacillus acidophilus* and yet similar in taste and physical properties to fresh milk, and having only a negligible quantity of free lactic acid was used by Myers.⁴⁵ The product is virtually a sweet whole milk in which viable cells of *Lactobacillus acidophilus* have been suspended in large numbers (in excess of 100 million per ml.). Growth of the organisms is held in check by keeping the milk cold. Since *Lactobacillus acidophilus* has a growth temperature limit at about 20°C.(68°F.) development of acid over a period of two to three days is prevented if the milk is held below 10°C.(50°F.). Data are presented to show that these organisms suspended in unfermented milk are capable of being implanted in the intestinal tract of white rats and of man. Experiments in which a number of individuals drank daily a quart of unfermented acidophilus milk were made to test out the effectiveness of such feeding in bringing about transformation of the intestinal flora. In the ten experiments on human subjects, successful implantation of *Lactobacillus acidophilus*, as determined by the plate method, was obtained in each case. In 12 of the 16 experiments a predominant *Lactobacillus acidophilus* flora was obtained by regular consumption of approximately one quart of unfermented acidophilus milk per day, no other modification of the ordinary diets of the subjects having been made.

Permanence of Results of Acidophilus Therapy. Since it has been quite definitely shown that implantation of *Lactobacillus acidophilus* in the intestines is largely dependent on the diet, one is not surprised to find that implantation may not be permanent. Kopeloff⁴⁶ found that the organisms remained for some time in the intestines after their ingestion in cases of diarrhea and constipation had been discontinued. One case was cited in which the benefits persisted for two years, three cases for over a year, and ten for three to six months. Other data on this question are given in

contiguous paragraphs. That the results of acidophilus therapy may be greatly influenced by the particular strain used seems to be indicated by the work of Sanborn,⁴⁷ who observed that a foreign strain of *Lactobacillus acidophilus* ingested in acidophilus milk almost completely suppressed the native strains. However, when the milk therapy was stopped, the foreign strain disappeared rather quickly. Under appropriate dietary conditions, the native strains frequently developed to greater concentration than before milk therapy.

Preparation of Acidophilus Milk. Much confusion has probably been caused by the use of preparations which were not properly prepared. Unless Rettger's technique for preparing acidophilus milk is followed, one cannot expect to secure the results which Rettger and his colleagues reported. This was emphasized by Rettger⁴⁸ in a paper before the American Public Health Association. He criticized many modifications which have been made in the preparation of the milk. He called attention to the fact that the use of such preparations would not yield results which could be compared with those resulting from the use of properly prepared milk.

Cheplin and Rettger's Acidophilus Milk. Cheplin and Rettger⁷ proposed the following procedure for the preparation of *Lactobacillus acidophilus* milk. Stock strains of the organism, preferably a mixture of strains, are grown sufficiently long in milk to produce light curdling in 24 hours. Usually this results from a shorter incubation period, hardly ever over 24 hours. Sweet milk is thoroughly sterilized under pressure after which it is inoculated with a mixture of pure cultures of *Lactobacillus acidophilus* and incubated at 37°C.(98.6°F.) for 12 to 24 hours. Strains which have been growing in milk for a time have to be used, since the freshly isolated strains are often inactive. After coagulation, the milk should be stored in the refrigerator.

Prucha and Brannon's⁴⁹ Modified Acidophilus Milk. These authors have described their acidophilus milk as follows: Skimmed milk of good quality is pasteurized in a glass-lined vat at 79.4°C.(175°F.) for 30 minutes, cooled to 37.8°C.(100°F.) and allowed to stand for three or four hours, repasteurized under the same conditions, cooled to from 37.8°C.(100°F.) to 38.9°C.(102°F.). It is then inoculated with a strong active culture of *Lactobacillus acidophilus* using at least three per cent of inoculum. When an acidity of .5 to .6 per cent is reached the milk is cooled to 15.6°C.(60°F.) and cream is added to give a fat content of one per cent with five to 10 per cent of a good lactic acid starter to improve the flavor. The milk is then passed through a homogenizer and over a cooler.

Eggston and Norman's⁵⁰ Modified Acidophilus Milk. These investigators claimed to have produced an acidophilus milk which was white in color, of a nonlumpy consistency, practically odorless, and in which the fat content could be regulated to suit the patient. One pint of tap water was placed in a liter flask. If one wished a sweet-tasting milk, a heaping tablespoon of lactose was added to the water which was then autoclaved for 20 minutes under 25 pounds pressure. The water was cooled and a pound tin of unsweetened evaporated milk was added to the flask using aseptic conditions. The mixture was then inoculated with ten ml. of a stock culture of *Lactobacillus acidophilus*, shaken, and incubated for 24 hours at 37°C.(98.6°F.). A soft curd was formed, slightly separated from the whey at the top. This was shaken and kept cool. The fat content may be varied by altering the amount of water.

Carlsson, Wertz, and Broadhurst's⁵¹ Modifications of Acidophilus Milk. Carlsson, Wertz, and Broadhurst reported favorable results obtained with 16 subjects with two

modifications of acidophilus milk. One was a mixture of *Lactobacillus acidophilus* and ordinary compressed yeast, obtained by inoculating autoclaved milk with pure cultures of these two organisms. The product was highly acid, often two to four times as acid as milk inoculated with acidophilus only. In the other modification, the milk was also autoclaved, before inoculating with acidophilus, until a caramel color and taste developed. This was used while still sweet, subjects who disliked sour milk finding it palatable. The results show that smaller doses than those heretofore recommended are successful when fresh, vigorous cultures are used, favorable results being obtained in such intestinal complications as constipation and "gas, headache, constant sleepiness."

Hughens'⁵² Procedure for Preparation of Acidophilus Milk. Hughens used materials and equipment which are found in bacteriological laboratories. He gave the following technic:

1. Fill the number of 500 or 1,000 milk bottles which are to be planted half full of water.

2. Place temporary cotton stoppers in the bottles.

3. Wrap the number of corks necessary in a piece of muslin.

4. Sterilize the bottles of water and the package of corks by steam under 15 pounds pressure for 30 minutes.

5. Remove the water and the package of corks from the sterilizer and allow to cool.

6. Evaporated milk is provided for the completion of the culture medium.

7. Each can of evaporated milk as it is used is flamed on one side of the top until it is hot enough to be sterile. When the heat expands the milk until there is a cracking noise, the can is shaken and the heat again applied. After the edge of the can has been sterilized a pointed instrument, which has been rendered sterile by flaming, is plunged through the sterile area in the top of the can. The hole made answers for an air hole. The can is turned to the opposite side and another area sterilized. The opening made on this side by the sterile pointed instrument is made large enough so that the milk will pour freely. A screw driver, old scissors blade, or file may be used for puncturing the cans.

8. The top of the bottle is flamed, and with a flamed pair of thumb forceps the temporary cotton stopper is removed and discarded. The top of the bottle is again flamed. The stopper of the culture is removed, the top of the bottle flamed, and about one ounce of the culture is poured directly into the bottle which has just been prepared. Fill the bottle with evaporated milk and stop with a sterile cork stopper.

9. After the bottles have been treated as described, place them in an incubator at 37°C.(98.6°F.) for 24 to 36 hours, the time depending upon the degree of sourness desired. Usually around 30 hours makes a palatable milk. A good product will show a smooth white clot and there will be no gas formation.

10. Place the milk in a refrigerator where it will keep palatable for a considerable time.
